THE Council of the Scottish Meteorological Society presented their report at the annual general meeting held yesterday. From the report we learn that a large work, which has been in course of preparation for some time, has just been completed, viz. averages of mean temperature and mean barometric pressure for the forty years ending with December 1895 have been calculated for each of the Society's 145 stations. It is not possible to over-estimate the importance of these averages in carrying on several of the more important departments of the Society's work, more particularly in the preparation of the monthly and quarterly report of Scottish weather. The very heavy work of recopying, on daily sheets, the hourly observations of the two Ben Nevis Observatories has now been virtually completed down to date. This result has been mainly secured by the aid of the grant of £100 obtained from the Government Research Fund last year. The large inquiry carried on by Dr. Buchan and Mr. Omond for some years on the influence of fog, cloud, and clear weather respectively, on the diurnal fluctuations of the barometer, has been extended into other regions, particularly the Arctic regions and Portugal, which furnish data of the utmost importance to the inquiry. Among the questions more immediately raised, as the investigation proceeds, is the influence on the pressure at the two observatories of the vertical distribution of temperature and humidity through the intervening stratum of air between the top and bottom of the mountain. The Council referred to the handsome donation of £1875 made to the Ben Nevis Observatories by the Trustees of the late Earl of Moray; they have by means of it been enabled to engage an additional clerk for the office, so that, for the next two or three years, Dr. Buchan's time may be largely set apart for the discussion of the Ben Nevis observations. It has further been resolved to establish a temporary station during the summer and autumn on the top of Meal ant' Suie, situated at a height of 2322 feet, and in the line of the two observatories. The object sought to be attained by this new station is a better knowledge of the vertical distribution, particularly during anticyclonic periods, of temperature and humidity through the aërial stratum between Fort-William and the top of Ben Nevis.

THE meteorological department of the library of Harvard College Observatory has become, by recent large accessions, one of the most complete collections of meteorological works in the United States. In the early history of the Observatory, many such works were collected by the first and second directors of the institution, Profs. W. C. Bond and G. P. Bond; and since

then the collection has continued steadily to increase. More recently, states the Harvard College Observatory *Circular*, No. 8, three large additions have been made to it: the general library of Harvard University has placed at the Observatory a great number of the meteorological works formerly kept at Gore Hall; the Blue Hill Meteorological Observatory has made a similar transfer; and the New England Meteorological Society, which has lately dissolved its organisation, has deposited the works contained in its library, and also the remaining copies of its own publications. Special efforts are now in progress to render still more complete the large collection which has resulted from these additions. It is hoped that the meteorological department of the library may be made so complete as greatly to increase its present value in aiding the studies of meteorologists.

IN spite of its limited resources, the British School at Athens contrives to initiate and carry out very valuable archæological work. The report read at the annual eeting of the supporters of the school, held on Monday, gave an encouraging account of the work of exploration and excavation accomplished during the past year. The financial position of the school, though still below that of its rivals, is now upon a footing which is comaratively satisfactory. The subscriptions, together with the Government grant of £500 per annum for five years, lead the Committee to believe that they may reckon upon an annual income of £1400 for some years to come. Of this it is estimated that about £1000 will be required for the current expenses of the school (including studentships), leaving about £400 per annum for excavations. But though the school stands in a better financial position than it has ever been before, its revenue is still modest as compared, for example, with the £3100 a year of the French school, which has, in addition, received a special grant of £30,000; the £2400 of the Germans, to whom also the Government has made the contribution of £40,000 for the excavations at Olympia; and the United States school, which enjoys £2000 a year. The school is, however, doing its best on its modest resources, and the archæological discoveries made in connection with it are valuable contributions to human knowledge.

PROF. H. A. NEWTON has been making a comparison between the mortalities of Yale graduates in the years 1701–1744 and 1745–1762, to see whether the changes of mode of living and comforts had any effect upon the vital statistics of the two groups of men (Yale, *Biographies and Annals*). By arranging the mortalities in decades of years from 15 to 75 years of age in the case of each group, it was seen that the group 1745–1762 showed a distinct increase of mortality per thousand lives between the ages of 15 and 35; an equality of mortality during the next ten years, and a decided diminution for the ages 46 to 75, when compared with corresponding periods in the group 1701–1744. It is a marked feature of the mortality statistics of American college graduates that there is excessive mortality in the years immediately following graduation. This, Prof. Newton thinks, is no doubt due to the strenuous efforts of young graduates to attain a good position in their profession. The later favourable experience in the ages from 45 to 75 is presumably due to the fact that they have by that time gained position, or else lost ambition. It would seem that this early strain was experienced by the graduates of the years 1701–1744 distinctly less than it was by the graduates of the eighteen years following. It would also seem that the corresponding strain for men between the ages 45 and 75 was much greater than for the later graduates, and perhaps that there had been a decided gain in the modes and comforts of life during the quarter of a century, which on an average separates the two groups of men.

THE literature of water-bacteriology is fast assuming well-nigh unwieldy proportions; almost the latest contribution to hand is an elaborate memoir in Spanish, from the Municipal Chemical Laboratory of Valparaiso, on an epidemic of typhoid fever in this city. Dr. Mourgues, who is responsible for the report in question, claims to have successfully tracked this serious outbreak to the water supplying the city. The chemical analyses already showed it to be badly polluted with sewage; and in this condition, without undergoing filtration, it was distributed for dietetic purposes. By resorting to all the most efficient methods at present at our disposal for the discovery of the typhoid bacillus in water, Dr. Mourgues tells us that he "discovered a bacillus which, according to the majority of the bacteriologists, is the cause of typhoid fever." He exhibits, however, some degree of caution in accepting his own conclusions, for he tells us that if it was not the typhoid bacillus, it was the *B. coli communis*, which, according to Rodet, G. Roux, and Vallet, is also capable of inducing typhoid fever. Dr. Mourgues has produced an able and interesting report quite apart from the credit attaching to his investigations; for he has brought together, in a brief and handy form, most of the principal work which has been done in recent years on the bacteriology of water in relation to the typhoid bacillus.

IN a letter communicated to the *Comptes rendus* (June 22), M. Moureaux gives a short account of some recent measurements of the magnetic elements which he has made in South Russia. In the neighbourhood of a village called Kotchetovka, at latitude 51° and longitude 6° 8′ east of Poulkowa, the extreme values of the elements determined in fifteen different stations, scattered over an area of about a square kilometre, were as follows:—

Declination	+58°	to	−43°
Dip	79°	to	48°
Horizontal force	0·166	to	0·589

In addition to the extreme largeness of these differences, it is interesting to note that the horizontal force attains in this region a greater value than that found at the equator. Since the dip is not less than 48°, it follows that the value of the total force in some parts of this region is extremely large. At another village (Potrovshojé), about fifteen kilometres to the south of the first, the values of the elements were:—Declination, +52° 56′; dip, 81° 45′; horizontal force, 0·09. A series of measurements showed that the dip attained a maximum value of 82° 13′ near this point, the value of the horizontal force corresponding to this maximum being 0·079.

THE Metopic Suture is the name given by anthropologists to the persistence of the frontal suture. Several investigators have attacked the problem of the significance of this suture, but the most thorough study is that by Dr. G. Papillault in the current number (tome ii. 3 sér. 1 fasc.) of the *Mémoires de la Soc. d'Anth. de Paris*. After a very detailed investigation, the author comes to the following general conclusions:—It has no sexual significance. The brain is the primary cause of metopism; not that metopics have an intellectual superiority over other people, but a superiority in the relative weight of their brain. There is a preponderance of complicated sutures and wormian bones in metopic crania, but these are less marked in the races in which the weight of the skull increases equally with that of the skeleton; in other words, in what one generally terms the lower races. Civilisation, in multiplying and knitting the bonds of social union, in augmenting in the struggle for life the power of the intelligence and in diminishing the preponderance of brute force, permits those who are intellectually endowed to live and prosper despite their muscular weakness, and thus it also becomes one of the most important factors of metopism.

THE publication of a special journal to care for the specific interests of physical chemistry, will commence in October of this year. This *Journal of Physical Chemistry* is to be issued upon the first of every month, except that in July, August, and September no number will appear. It will contain articles embodying original research in all branches of experimental and theoretical physical chemistry; and this matter will be supplemented by reviews of the current literature of the subject. All communications concerning articles should be addressed to the *Journal of Physical Chemistry*, Ithaca, N.Y. The editors are Wilder D. Bancroft and Joseph E. Trevor, assistant professors of physical chemistry in Cornell University.

IN a recent number of the *Comptes rendus* (June 22), MM. Lortet and Genoud give an interesting account of their experiments on the effect of Röntgen rays on tuberculosis. Although still incomplete, these experiments seem to indicate that we may have in the new light a remedy for tuberculosis. Eight guinea-pigs were inoculated with the virus of tuberculosis. Three of these were exposed daily for at least an hour to the influence of powerful Röntgen radiations, from April 25 to June 18. The other five were not so treated. In the latter, abscesses were produced and the health deranged. In the three treated with Röntgen rays no abscesses were formed, the health remained good, and the animals increased in weight.

THOUGH examinations of the contents of stomachs of crows have shown that these birds feed very largely upon noxious insects and other injurious animals, the result apparently does not prove that the crow is a friend to the farmer. A note in the *North British Agriculturist* reports that much damage has been committed in turnip fields in Annandale during the past few days by crows. The crows, in their search for wire-worms, pull up the young turnips, probably finding a worm at the root of one out of 150 or 200 pulled up. The fact shows the importance of avoiding conclusions as to the usefulness of a bird merely from determination of food habits. The farmers of Annandale would probably have been better pleased if the crows had fed upon the young turnips instead of wire-worms, for the destruction would not then have been so great.

THE third part of Mr. John W. Taylor's valuable "Monograph of the Land and Freshwater Mollusca of the British Isles" has just been published by Messrs. Taylor Brothers, Leeds. It deals with the morphology and anatomy of the animal inhabitants of shells, and is illustrated just as clearly and liberally as the previous parts, in which the shells and their auxiliary appendages were described. Conchologists should be grateful to Mr. Taylor for the pains he is taking to provide them with a trustworthy and instructive work upon British Land and Freshwater Molluscs.

MESSRS. TRUSLOVE AND HANSON have in the press an illustrated work on "The Natives of Sarawak and British North Borneo," by Mr. Ling Roth. The work will be published in two volumes, and the edition will be limited to seven hundred copies. No complete work dealing with the natives of British Borneo exists, though the history of that very interesting colonial possession could furnish material for a dozen romances. How very completely Sir James Brooke, and his nephew and successor as Rajah (Sir Charles Brooke), have changed the customs of the Dyaks, should be known to all who are interested in methods of establishing British colonies, and of improving the condition of the people who inhabit them. Mr. Ling Roth's work will deal with the people of British Borneo from many points of view, and it promises to be a valuable contribution to anthropology.

THE South London Entomological and Natural History Society has sent us the abstract of the *Proceedings* for 1895, together with the address of the President, Mr. T. W. Hall. Though unpretentious in character, the Society has assisted in the diffusion of biological knowledge by its meetings and collections, and its publications always contain material of interest to every one interested in natural history. Another Society, which has just sent us its Report for 1895, is the Manchester Microscopical Society. First among the contents of this publication is an address by the President, Prof. F. E. Weiss, on "The Influence of External Conditions on Reproductive Processes in Plants." The subjects of other papers are: some insect pests, by Mr. A. T. Gillanders; the organs and function of reproduction in insects, by Mr. F. Paulden; notes on Hydrozoa and Polyzoa, by Mr. J. Smith; photo-micrography, by Mr. E. H. Turner; and the animal life of the Coal-measures, by Mr. Herbert Bolton. May such Societies as these of South London and Manchester long exist to stimulate and encourage biological and microscopical research.

WE have on our table several new editions of scientific books. First among these is the seventh edition of Dr. Benjamin Williamson's "Elementary Treatise on the Integral Calculus" (Longmans, Green, and Co.). The chapter on the calculus of variations has been considerably enlarged, and a brief discussion added on the application of that calculus to double and multiple integrals. A short chapter on the sign of substitution has also been introduced. Messrs. A. and C. Black have published the second edition of "Rheumatism: its Nature, its Pathology, and its successful Treatment," by Dr. T. J. Maclagan. Twenty years ago the author introduced salicin to the medical profession as a remedy in acute rheumatism. In the first edition of this work, published in 1881, he expounded the miasmatic theory of rheumatism, and offered an explanation of the manner in which the salicyl compounds produce anti-rheumatic effects. In the present edition the whole subject of the pathogenesis of rheumatism, and the curative action of the salicyl compounds, is gone over again. The book thus contains the history of a remarkable and beneficial change in the treatment of a disease which was the despair of a past generation of physicians. A fifth edition of a "Coloured Vade-mecum to the Alpine Flora, for the use of Tourists in Switzerland," has been published by Albert Raustein, Zürich. The book contains 170 coloured illustrations of Alpine flowers, accompanied by descriptive text in English, French, and German, by L. Schröter and Prof. C. Schröter. The book should be in the hands of every lover of Alpine flowers; and it will be found a pleasant companion to the many tourists who, during the next few months, will wander about the Alps. The pleasing and elegant "Ros Rosarum, ex Horto Poetarum," by E. V. B., the second edition of which has been published by Mr. Elliot Stock, contains a wealth of poetic extracts having the rose for their theme. The quotations show that the rose has been honoured and admired in almost all times and places. The twenty-eighth edition of "Skertchly's Physical Geography," revised by Mr. J. H. Howell, has been published by Mr. Thomas Murby. Mr. Howell has made a number of requisite alterations in the text, but the book is still badly illustrated.

THE annual Report (1894-95) of the Director of the Field Columbian Museum, Chicago, has been received. A large number of accessions to the collections have resulted from the expeditions sent out by the Museum. In October 1894, Mr. Allison V. Armour, of Chicago, invited Dr. Millspaugh, of the Department of Botany, and Prof. Holmes, of the Department of Anthropology, to accompany him on his yacht to Havana, Progreso, the islands on the east coast of Yucatan, Laguna di Terminos and Vera Cruz. On this expedition, Dr. Millspaugh's work resulted in the acquisition of nearly eight hundred speci-

mens in botany, which formed the types included in his "Flora of Yucatan," and considerable material for exchange to augment the small herbarium in his department. He also secured about four hundred specimens in zoology, principally conchology, and a number of excellent negatives relating to geology, botany, ethnology and travel. Prof. Holmes secured altogether about one thousand specimens in archæology from Yucatan, Chiapas, Oaxaca, Vera Cruz and the valley of Mexico, and made a number of important observations. An expedition to San Domingo, conducted by Mr. Geo. K. Cherrie, Assistant Curator in the Department of Ornithology, resulted in the collection of 1958 bird skins, 16 mammals, 80 reptiles, and a number of specimens of fish and Crustacea. Among the birds, two species proved new to science, and a number of others are very interesting as representing rare and little-known forms. Captain Miner W. Bruce was fitted out by the Museum for an expedition to Alaska and Siberia in June 1894, and he acquired valuable ethnological material from North Alaska. A number of minor expeditions were also organised in the interests of the Museum, and they have resulted in numerous additions to the collections in different departments, as well as the acquisition of information of great scientific value, which information is made known through the admirable series of publications issued by the Museum.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, a White-throated Monitor (*Varanus albogularis*) from South Africa, presented by Sir Gilbert Carter; a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. Henry Russell; a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mr. E. Kirby; a Striped Hyæna (*Hyæna striata*) from Arabia, presented by Mr. C. A. Osborne; a Hamster (*Cricetus frumentarius*), European, presented by Miss Hilton; three Yellow-bellied Liothrix (*Liothrix luteus*) from India, presented by Mr. Robert E. Graves; an Iceland Falcon (*Hierofalco islandus*) from Iceland, eight Horsfield's Tortoises (*Homopus horsfieldi*) from Central Asia, two Giant Toads (*Bufo marinus*) from Brazil, a Reticulated Python (*Python recticulata*) from Malacca, deposited; two Lettered Aracari (*Pteroglossus inscriptus*) from Para, a Black-necked Swan (*Cygnus nigricollis*) from Antarctic America, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), two Glossy Ibisis (*Plegadis falcinellus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE CLUSTER IN COMA BERENICES.—The results of a triangulation of the more conspicuous stars in this group have been recently issued from the astronomical observatory of Yale College. This contribution to a class of observations that is now receiving much attention, has been made with the heliometer by Mr. F. L. Chase at the suggestion of Dr. Elkin. The instrument employed is the same that Dr. Elkin used in his measurements of the Pleiades group, and the method of reduction follows generally the same lines that were then adopted; but the different configuration of the fundamental stars on which the measures are based, has enabled the observer to dispense in some degree with measures of position angle, the less trustworthy coordinate in heliometer observations, and to rely upon measures of distance from six selected stars, five of which form nearly an equilateral pentagon, the sixth being approximately in the centre. Two lines of stars roughly crossing the pentagon at right angles, and extending some six degrees, have been utilised for determining the scale value. The final result is to give the coordinates of thirty-three stars (Equinox 1892·0) limited to about the 8·5 mag., below which magnitude the most satisfactory observations cannot be made with the Yale instrument. An examination of the probable errors of the measures, classified according to the magnitude of the stars, does not disclose any law dependent on brightness, so that Mr. Chase has not overstepped prudence in this respect. At the same time the position of so many well-scattered points of reference has been determined, that it should be an easy task, and one worthy of accomplishment, to derive the places of the remaining and fainter stars of the group by means of photography.

OBJECTIVE GRATINGS.—Messrs. Hall and Wadsworth describe in the June number of the *Astrophysical Journal* the results of a fairly successful application of an objective grating, constructed on the original Fraunhofer method, and attached to a 12-inch photographic object-glass, whose ratio of aperture to its focal length is as 1:18. Two screws 27 cm. long, and with 63 threads to the centimetre, were cut in two along their axes, and the half-screws mounted, parallel to each other, on the opposite sides of rectangular frames. Copper wire was wound across in the successive threads, and soldered to the screws so as to produce a grating. When applied to the telescope, photographic spectra of both the first and second order could be obtained, and cases are quoted showing the agreement of the deduced wave-length with Rowland's values. One of the difficulties experienced in the use of this form of grating arises from the wind disturbing the lines of the grating, an annoyance which, it is suggested, might be prevented by soldering light rods across the wires parallel to the half-screws. The time required for exposure with objective gratings is of course longer than with the objective prism; but against these two disadvantages is to be set the comparative small cost of construction. In the one used in the experiments at Chicago, the cost was only one-thirtieth of that of an equally large objective prism of small angle, and evidently the advantage on the side of economy increases as the aperture increases. In the case of the Yerkes telescope, it is computed that the grating would cost about the two-hundredth part of the prism of the same size.

DISTORTION OF THE EARTH'S SURFACE.—Under the title of "An Earth-bending Experiment," Prof. H. H. Turner gives a description of a series of observations undertaken at Oxford by Prof. J. Milne (*Observatory*, July). In his investigation of terrestrial disturbances in the Isle of Wight, Prof. Milne found evidence of their being due to several causes. For instance, some are due to real local earthquakes on a small scale, some owing to faint echoes of very distant earthquakes, while it appears that others may have their origin in the various states produced on the surface of the ground by meteorological causes. These last have specially attracted attention, as it is quite possible that the considerable load represented by a shower of rain or snow, or a heavy fall of dew, may be capable of bending the surface of the ground to such a degree as to affect the stability of any astronomical instruments not having very deep foundations. In looking for these effects, it might be expected that tilts due to rainfall, though irregular, would show some evidence of an *annual* periodicity, while those produced by dew would show a *diurnal* variation. To test whether any of these causes might have an appreciable disturbing effect, the University Observatory at Oxford was chosen as being particularly suitable, standing alone in a grassy park. The instruments for detecting and recording any difference of level consisted of one of Prof. Milne's horizontal pendulums and the level of the Barclay transit circle. The effect of a sudden shower was imitated by securing the services of seventy-six people, who were marched, in various degrees of compactness, up to and away from the slate slab supporting the registering apparatus. The result of these experiments was that a small depression was observed, always towards the crowd, the maximum value, however, being only 0″·5, when the load was concentrated and close to the instrument. The load employed being estimated greater than is likely ever to be produced by rain, &c., it is concluded that on that particular site at least no disturbance due to meteorological causes need be feared.

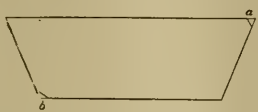
ON THE LIQUATION OF CERTAIN ALLOYS OF GOLD.[1]

THE molecular distribution of the metal in alloys of gold and of metals of the platinum group has been described by me in several papers, the most important of which has been published in the *Philosophical Transactions*. New

[1] Abridged from a paper read before the Royal Society, May 7.

interest in the subject has however arisen in connection with the extraordinary development in various parts of the world, and especially in South Africa, of certain processes which are now employed for extracting gold from its ores. Their use has been attended with the introduction into this country of a series of alloys of gold and of the base metals, which have hitherto rarely been met with in metallurgical industry. The base metals associated with the gold in these cases are usually the very ordinary ones lead and zinc; but their presence in the gold has given rise to unexpected difficulties, as the distribution of the precious metals in the ingots which now reach this country is so peculiar, that it is not possible to estimate the value of the ingots by taking the pieces of metal required for assay, by any of the well-known methods at present in use.

Investigation of the cause of the singular molecular arrangement of the ingots, has revealed many facts of scientific as well as industrial interest, which the author describes at length. The following case of an ingot of gold may be taken as typical.



Four assays were made on a portion of metal cut from the points marked *a*, at the top of the ignot; the highest of the results of assay indicated that 664 parts of gold were present in 1000 parts of the alloy, while the lowest assay gave only 465 parts. On the other hand, three assays on a piece of metal cut from the bottom of the ingot, at *b*, gave 652 parts of gold in 1000 as the highest, and 332·5 as the lowest. Clearly, therefore, the action of gravity does not explain the distribution of the precious metal.

The ordinary course, where divergent results of assay are obtained on portions of metal cut from such an ingot, would be to melt the entire mass, and take a "dip" assay piece, that is, to remove a portion of metal from the well-stirred fluid mass. This was done in all the cases cited in the paper here abridged, and as regards the mass of gold to which reference has just been made, assays on the portion of metal removed from the fluid mass gave results which were still very conflicting, the lowest assay showing the presence of 562·3 parts of gold, and the highest 653·5. It was evident therefore, that rearrangement could take place within the limits of a fragment of metal which did not weigh more than a few grammes.

The only method of ascertaining the value of the ingot consisted in separating the precious and base metals in mass, and the result of this operation showed the value of the ingot to be £1028, while the value, as calculated from the average of the assays previously made, would only have been £965, or a difference in value of £63 on an ingot weighing 12·223 kilograms. The importance of the question from an industrial point of view will at once be recognised when it is remembered that gold to the value of many millions sterling of the quality represented by the above results, now reaches this country annually.

Coming now to the scientific side of the problem, analysis of the ingot, to which reference has been made above, showed that it contained the following metals in addition to gold:

Silver	8·1	per cent.
Lead	16·4	,,
Zinc	9·5	,,
Copper	4·0	,,
Iron	·3	,,

Suspicion at once fell on the lead and zinc as disturbing elements, and their influence was systematically investigated by a lengthy series of experiments, in the course of which gold alloys, containing different proportions of gold and of impurities, were cast in spherical moulds two and three inches in diameter, the solidified masses being explored by assays made on metal representing all parts of the mass. The general result of these experiments was to show that lead exerts a greater disturbing influence than zinc. The problem was then attacked from a different point of view. I availed myself of Roberts-Austen's method of fixing the solidifying points of metals on "cooling curves" obtained by the aid of thermo-junctions connected with autographic recorders. Such curves showed that a triple alloy of lead, gold, and zinc has three "freezing points." The mass sets as a whole at a single main point of solidification, but the lead and the zinc associated with some gold retain a certain amount of individual independence, and by falling out of solution, separately destroy the uniformity of the mass, even though the mass itself be small.

After a long series of experiments, a metallic solvent which would enter into union with the gold, the zinc, and the lead was sought. Silver proved to be such a solvent, and solidified alloys of gold containing not more than 30 per cent. of lead and of zinc, may be made practically uniform in composition by adding 15 per cent. of silver to the mass when fluid. The result is singular, as it shows that there are cases in which the uniformity of a gold alloy may be improved by lowering its standard fineness; and another proof of scientific interest is afforded of the fact that alloys behave like saline solutions.

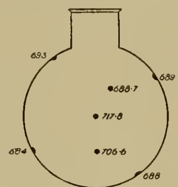


FIG. 1.—Gold 700 parts, lead 300 parts; weight about two kilograms.

The result shows a decided tendency of the gold *to liquate to the centre of the mass.*

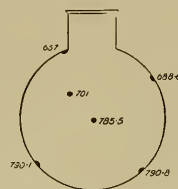

FIG. 2.—Gold 75 parts, lead 15 parts, zinc 10 parts; weight about two kilograms.

There is evidence of rearrangement by liquation in this case which sends gold to the centre, but the result is complicated, as gravity appears also to send gold to the lower portion of the spherical mass.

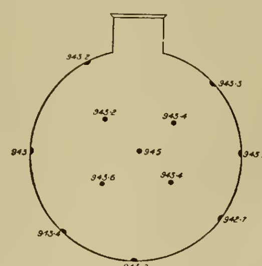

FIG. 5.—Gold 95 parts, zinc 5 parts; weight 4·430 kilograms.

A slight but decided tendency of liquation of gold towards the centre.

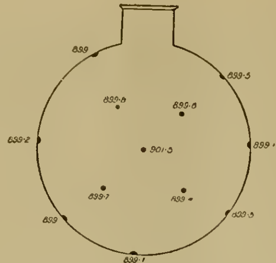

FIG. 7.—Gold 90 parts, zinc 10 parts; weight 4·200 kilograms.

This shows that there is still a tendency in this gold alloy with 10 per cent. of zinc to become enriched towards the centre.

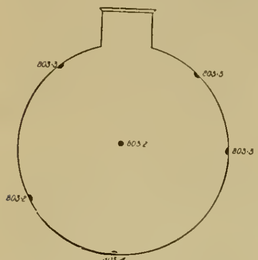

FIG. 9.—Gold 77·5 parts, silver 7·5 parts, zinc 15 parts; weight 3·930 kilograms.

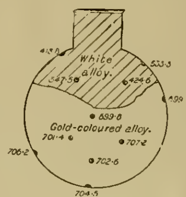

FIG. 11.—Gold 63 parts, silver 7 parts, lead 20 parts, zinc 10 parts.

Very marked separation takes place here, the difference at various points of the sphere being very remarkable, and forcibly illustrating the difficulties to which reference is made at the commencement of this paper.

As, however, it appears, that when a certain amount of silver is present, the irregularity in composition disappears, this mixture of—

Zinc...	10
Lead	20
Silver	7
Gold	63

was alloyed with more silver, so that it contained 15 per cent. of silver (nearly half the united amounts of zinc and lead present in the alloy).

This, cast into the 3-in. spherical mould, showed the following results at the points indicated. In *appearance*, the metal, when sawn in two, was homogeneous.

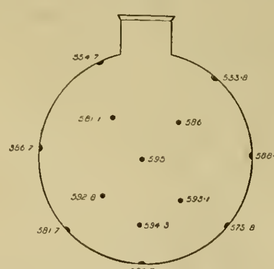

FIG. 12.—Alloyed so as to contain 15 per cent. silver; weight 3·450 kilograms.

There is here still evidence of liquation of gold towards the centre, but comparison of Fig. 12 with that which immediately precedes it will show how greatly the arrangement of the alloy has been modified by the presence of the additional 8 per cent. of silver. The proportion of silver in this alloy was proved by assay to be 15·5 per cent.

As there was still evidence of liquation, the metal was cast with still more silver, making 20 per cent. of silver in all. The alloy, when cast into a mould, proved to be almost uniform in composition, the difference between the centre and the extreme portions being very slight.

Liquation had practically ceased, a fact which proves incontestably that silver is the solvent for the base metals, zinc, and lead, when they are alloyed with gold.

Conclusions.—(1) Alloys of gold with base metals, notably with lead and zinc, now often met with in industry, have the gold concentrated towards the centre and lower portions, which renders it impossible to ascertain their true value with even an approximation to accuracy.

(2) When silver is also present these irregularities are greatly modified.

The method of obtaining "cooling-curves" of the alloys shows that the freezing points are very different when silver is present in the alloy and when it is absent from it.

(3) This fact naturally leads to the belief that if the base metal present does not exceed 30 per cent., silver will dissolve it and form a uniform alloy with gold.

(4) This conclusion is sustained by the experiments illustrated by Figs. 9, 11 and 12, which, in fact gradually lead up to it, and enable a question of much interest to be solved.

EDWARD MATTHEY.

THE ATOMIC WEIGHT OF OXYGEN.[1]

THIS monograph embraces a complete collection of the results obtained by Dr. Morley while working on this subject, and gives a detailed account of the various apparatus used. The experiments described extended over a very lengthened period. They consisted of the determination of the ratio between oxygen and hydrogen by two distinct methods, viz. by actually weighing the gases and by synthetising water. In all his experiments Dr. Morley dealt with far larger volumes of purer gases than previous experimenters had used, and in weighing them he reduced with surprising completeness every possible source of error. In his work on the synthesis of water, Dr. Morley succeeded in weighing the hydrogen and oxygen burned, and also the water produced thereby, achieving an exactness not attained by any previous experimenter, as none before had weighed all three factors. All experiments dealing quantitatively with gases are naturally extremely difficult, but Dr. Morley has, by paying attention to every detail, brought each process to a great pitch of accuracy.

The major corrections that were introduced into the determinations were as follows.

(1) The expansion of the glass of the globes.
(2) The errors of the mercurial thermometers.
(3) The deviation of the mercurial from the hydrogen thermometer.
(4) The difference between the coefficients of expansion of oxygen and hydrogen.
(5) The elevation of the cistern of the barometer above the centre of the globe when reading pressure.
(6) The correction of the scale of the barometer.
(7) The force of gravity at the laboratory.

In weighing the gases Dr. Morley employed large glass globes varying in capacity from nine to twenty-one litres. All data connected with the capacity of these were accurately determined. As the globes were so large it was found impossible to weigh them full of water to measure their capacity, and a different method had to be adopted. The globes were first weighed in air, then sunk in water, the weights being determined to keep the globes immersed; lastly the globes were filled with water, and again weighed in water. From these were obtained the external volume, the solid contents, and the capacity within ·02 per cent. In introducing a correction for the compression of the globes when exhausted, Dr. Morley devised an exceedingly ingenious plan. The compression itself was determined by placing the globe in a copper cylinder, which was then closed

1 "On the Densities of Oxygen and Hydrogen, and on the Ratios of their Atomic Weights," by Dr. E. W. Morley. *Smithsonian Contributions to Knowledge*, No. 980. (Washington, 1895.)

and filled with water. A small tube led from the cylinder to a burette containing water. When the globe was exhausted the compression was measured by the amount of water run into the cylinder from the burette. Each globe was provided with a counterpoise of equal external volume when exhausted. A pair of small flasks were then made, the difference between whose volumes was equal to the amount of compression just measured, and whose weights in vacuo were equal.

For example, the actual compression of one globe was 1·27 cc. The two small flasks were made 2·08 and ·81 cc. in volume and of the same weight when weighed in vacuo; therefore when weighed in air they differed in weight by the weight of 1·27 cc. of the air at the time, taking into account the true value of the weights employed. When the globe was exhausted it was weighed against the counterpoise which had the same volume. When it was full of gas it was tared with the ·81 cc. flask against the counterpoise and the 2·08 cc. flask; the *true* weights of the globes therefore suffered equal additions, with the result that the *apparent* difference in weight would be the *true* difference as expressed by brass weights in air.

The measurement of pressure and temperature, Dr. Morley took especial pains to make as accurate as possible. In the many series of experiments which are comprised in this great research, different methods were adopted of measuring these values. When thermometers were used great care was taken in determining their errors, and in the calculation of the pressures the value of the force of gravity as actually determined at Dr. Morley's laboratory was used.

Dr. Morley's determinations are divided into four series.

The first series consists of the determination of the weight of one litre of oxygen.

The second series consists of a similar determination for hydrogen.

The third series contains some experiments to determine the volumetric composition of water.

The fourth is a series of syntheses of weighed quantities of water from weighed quantities of oxygen and hydrogen.

The first series of determinations are those of the weight of a litre of oxygen under standard conditions. Three different methods were adopted.

In the first the temperature and pressure were directly determined by use of thermometers and a manobarometer.

In the second method the temperature and pressure were not directly determined, but made equal to those of a standard volume of hydrogen.

In the third method the pressure was alone read, the temperature being that of melting ice.

The oxygen for this series of experiments was obtained from potassium chlorate. The salt was placed in a hard glass tube in a combustion furnace; this tube was joined to the rest of the apparatus by means of a ground joint cemented with wax. Dr. Morley made a point of using no rubber connections in any of his experiments, rightly observing that even though the leakage may be exceedingly small, still the extra trouble entailed by fusing all joints together is worthily bestowed. Dr. Morley says there is no reason to doubt the purity of this oxygen; nitrogen he sought for particularly, and found quantities varying from 1/12,000th to 1/5,000,000th, which are quite negligible, considering the closeness of the atomic weights of the two gases.

Dr. Morley discusses the question of mercury vapour, and reasons from his experiments on hydrogen that the error is not greater than the ten- or twenty-thousandth part of the density of oxygen.

The pressure in these experiments was measured by means of a manobarometer, which consisted of a barometer and two gauges mounted in the same trough of mercury. One of these gauges was used for oxygen and the other for hydrogen, the experiments on which were carried out at the same time. The barometer and gauges were placed in a cistern of water with plate-glass sides. In front of each tube, and in contact with it, was a glass millimetre scale. The three scales were adjusted so that their zero points were all on the same level. The cathetometer used for reading had two telescopes, each with a micrometer eyepiece. The accuracy of reading was found to be within 1/100th mm.

In weighing the globes Dr. Morley met at first with great difficulty, owing to currents of air disturbing the globes. Their effect was, however, almost destroyed by hanging the globes in a sheet-iron box, which was in its turn placed in a non-conducting chamber under the balance. The balance was one of Becker's make, and had never been used for any other purpose.

The mean of nine determinations by this method of the weight of a litre of oxygen is

$$1 \cdot 42879 \text{ gr.} \pm \cdot 000034.$$

In the second method of weighing oxygen, the pressure and temperature were made equal to those of a standard volume of hydrogen. The preliminary part of this process was to fill a globe with pure hydrogen, and measure the pressure exerted by the gas on one leg of a differential manometer. This instrument was of the ordinary **U** shape, adjustment of the mercury being made to two needle-points, one in each limb. The globe containing the oxygen was then attached to the opposite limb, and the pressure adjusted till exactly equal to that of the hydrogen. A new balance was employed in these determinations, purchased especially for this work, and lent Dr. Morley by the Smithsonian Institution. Weighing was performed by reversal, the relative position of globe and counterpoise being changed by mechanical means.

Dr. Morley publishes fifteen determinations of the weight of a litre of oxygen by this method. The mean is

$$1 \cdot 42887 \text{ gr.} \pm \cdot 000048.$$

The method employed in the third series of determinations was to determine the pressure of the oxygen by means of the syphon barometer, the temperature being 0° C. The globe was immersed in ice, the layer of ice all round the globe being 30 centimetres thick. The globe was then exhausted and oxygen admitted, and its pressure measured. After weighing the globe was again exhausted and again weighed, the difference being taken as the weight of the oxygen. The reason for this procedure was the fact of the globe being exposed to the action of water for such a long time.

As a mean of twenty-four experiments, Dr. Morley gives

$$D = 1 \cdot 42917 \text{ gr.} \pm \cdot 000048.$$

We have, therefore, the following three mean results by the three different methods.

By use of thermometer and manobarometer	1·42879 ±	·000034
By compensation	1·42887	·000048
By use of ice and barometer ...	1·42917	·000048

In computing a final mean from these, Dr. Morley discusses the relative reliability of the results. He gives double weight to the third method, for, though involving more accidental errors, it involves no constant error common to the other methods.

Dr. Morley gives his final value for the weight of 1 litre of oxygen measured at 0° and 760 mm. at sea-level, and 45° lat., as 1·42900 gr. ± ·000034.

The second part of Dr. Morley's paper deals with his determinations of the weight of 1 litre of hydrogen under standard conditions.

Five series were made. In the first, pressure and temperature were measured; in the second, pressure only was measured, the temperature being equal to that of melting ice; in the third, the hydrogen was weighed in combination with palladium before introduction into the globe. The fourth and fifth were repetitions of the third.

The first series of determinations were carried out in exactly the same manner as the first series with oxygen, indeed at the same time. The hydrogen was prepared by the electrolysis of dilute sulphuric acid.

Dr. Morley adopted elaborate methods to measure the impurity in the hydrogen. He introduced a correction for the nitrogen found until, owing to an improvement of the apparatus, this percentage of nitrogen became so small as to be entirely negligible.

The mean of fifteen results obtained by this method is

$$D = \cdot 089938 \text{ gr.} \pm \cdot 000007.$$

The second method was to read pressure only, the temperature being 0° C. The details are exactly the same as in the similar case with oxygen.

The mean of nineteen experiments is

$$D = \cdot 089970 \pm \cdot 000011.$$

The third method, that of weighing the hydrogen contained in palladium, is one that is far more likely to prove accurate than methods depending on the weighing directly of a known volume

of hydrogen. For in the best case the weight of the globe was 600 times the weight of the hydrogen contained in it. The great advantage, however, to be gained from this method is the absence of any error introduced by mercury vapour, for it would have no effect on the weight of the hydrogen, and the volume and pressure of the residual mercury vapour are far too small to influence results. Dr. Morley has given especial attention to this method, and has brought it to a very great pitch of accuracy.

The palladium was placed in a tube which could be connected with the apparatus by a ground-glass joint. When the palladium was charged with hydrogen the tube was weighed. Connection being now made, a fusible metal plug, which took the place of a stop-cock, was melted, and the hydrogen passed into the globes. The tube was afterwards weighed, the difference giving the weight of hydrogen, usually about 3·7 grammes. This was found sufficient to fill three globes.

The mean of eight results in one series is

$$D = \cdot 089886 \pm \cdot 0000049.$$

The mean of four results in a second series is

$$D = \cdot 089880 \pm \cdot 0000088.$$

The mean of eleven results with a new apparatus,

$$D = \cdot 089866 \pm \cdot 0000034.$$

Dr. Morley gives as his final result for the weight of one litre of hydrogen under standard conditions,

$$\cdot 089873 \pm \cdot 0000027 \text{ gr.}$$

The third part of the paper deals with the determination of the volumetric composition of water. The electrolytic gas was produced in a voltameter, whose loss of weight gave the weight of gas used. This gas was admitted into globes of known volume, plunged in ice, where its pressure was measured. From these it was transferred to an eudiometer and exploded. The weight of gas usually dealt with was about 23 grammes. The explosion of the gases was carried on in a eudiometer, where all but 1/100th or 1/1000th part of the gas could be exploded out of contact with mercury. In all Dr. Morley's results he found excess of hydrogen, due to secondary reactions in the voltameter.

The mean value determined by ten experiments of the ratio of the excess of hydrogen to the whole combined volume of hydrogen and oxygen is ·000293. This value $\times$ 3 = ·00088 gives a correction to be applied to the ratio of hydrogen and oxygen, in order to obtain the ratio of volumes of hydrogen and oxygen that would combine without residue.

The mean of the ten experiments gives the value of the density of the electrolytic gas as

$$= \cdot 535510 \pm \cdot 000010.$$

In calculating the ratio of combining volumes, Dr. Morley takes into account the deviation of the mixed gases from the density computed by Boyle's law, and also the values of the constant a in Van der Vaals's equation. He obtains the ratio of mixture to be 2·000357, which, corrected for known excess of hydrogen, gives ratio of combining volumes to be

$$2 \cdot 00269.$$

The fourth and last portion of the experimental portion of the paper deals with the syntheses of water from weighed quantities of oxygen and hydrogen. The hydrogen was weighed, absorbed by palladium, the oxygen weighed in a globe, and the two were combined together in a combustion apparatus, whose gain in weight gave the weight of water produced. The quantity of hydrogen used was about 42 or 43 litres; the measured residue of uncombined gas varied from 1/100th to 1/10,000th of quantity concerned. The combustion apparatus was plunged in water during the union of the two gases, in order to keep it cool. This process took about one and a half hours, and was carried on as far as possible. The remaining gas in the various parts of the apparatus was pumped out and analysed, the combustion apparatus being kept in a freezing mixture, to keep as low as possible the vapour pressure of the water. The rest of the process needs no description.

As regards two possible sources of error which have been suggested, Dr. Morley proved conclusively that his hydrogen from palladium contained no water, and that his phosphorus pentoxide absorbed no oxygen.

As the mean of twelve experiments, Dr. Morley gives the atomic weight of oxygen to be very nearly

$$15 \cdot 879.$$

In collating all the results of his experiments, Dr. Morley gives the following values:

Weight of one litre of oxygen	1·42900
Weight of one litre of hydrogen	0·089873
Atomic weight of oxygen (chemical method) ...	15·879
Molecular weight of water (chemical method)...	15·879
Atomic weight of oxygen (physical method) ...	15·879

The probable accuracy of Dr. Morley's work appears to be exceedingly high, for he has in several cases spent especial trouble and time in eliminating hitherto constant sources of error. The extremely ingenious forms of apparatus he used for his many determinations are especially worthy of remark; and these, together with the extraordinary care bestowed in their use, combine to make the whole rank among the finest investigations of modern science.

E. C. C. BALY.

SCIENCE IN THE MAGAZINES.

THE relation of complexion to disease is discussed by Dr. John Beddoe, F.R.S., in the course of a paper in *Science Progress*. Baxter's great work on the medical statistics of the Civil War contains evidence as to the greater liability of blonds to certain classes of disease (in America at least). It follows from this that the blonds in America have less chance than the brunets of contributing their due proportion to the next generation, and therefore the blonds ought to diminish relatively, and the brunets to increase.

As bearing upon this, it appears that of accepted soldiers from among the white natives of the United States, 66 per cent. were light and 34 dark complexioned, but the proportion for English, Irish, and Germans is 70 to 30. Thus, Dr. Beddoe points out, the men of American birth yielded a larger proportion of brunets than those of any of the nations that had contributed to their ancestry, which is nearly equivalent to saying that the Americans are more generally dark complexioned than their ancestors were. Statistics as to the colours of school children of Germany, Austria, Switzerland, and Belgium, and of adults in Italy and the British Isles, seem to furnish sufficient evidence that in a great part of Europe the citizens are darker than the peasantry. Why the blond type should be more susceptible than the brown to the malign influences of urban life is a difficult question to decide.

Other articles in *Science Progress* are:—"Prehistoric Man in the Eastern Mediterranean," by Mr. J. L. Myres; "The Graptolites," by Mr. J. E. Marr; "Insular Floras," by Mr. W. B. Hemsley; and "Recent Discoveries in Avian Palæontology," by Mr. C. W. Andrews.

There are several articles in the *Contemporary* to which attention may be directed here. Mr. Phil Robinson describes "The First Nest of a Rookery," in a pleasantly-written paper, but the interpretations of his observations are made too much from the humanistic point of view. Dr. Lennox Browne attacks "The Antitoxin Treatment of Diphtheria," his criticism being based mainly upon the Report of the Metropolitan Asylums Board, summarised in these columns in April last (vol. liii. p. 524). He claims that the mortality of cases treated by antitoxin at the London hospitals in 1895 is but a trifle lower than that of the previous year, and is in excess of what has been obtained in individual hospitals of the series whence the Report is issued; and, also, that this improvement has not been due to the serum treatment, but rather to increased vigilance and nursing care. Some "Girls' Technical Schools on the Continent" are described by Marion Mulhall. The article shows how the technical instruction of girls now takes a front rank in the cares and duties of many municipal authorities in Holland, Belgium, Germany and Austria.

Sir W. M. Conway describes in *Scribner* his walk of "A Thousand Miles through the Alps," and concludes his narrative with a comparison between Switzerland and the Tyrol from a traveller's point of view, much to the advantage of the latter. He says, and there are many ready to corroborate his statements, "Whereas travel in Switzerland is exploited by hotel-keepers and organised in their interests, the Tyrol is, through the agency of the powerful German and Austrian Alpine Club, organised by travellers themselves in their own interests. In Switzerland, traps are laid for the tourist's francs; in the Tyrol, every effort is made to spare his pocket." The Tyrol is far ahead of Switzerland in climber's food, in mountain huts,

and in all other facilities for mountaineering away from crowds of tourists. "In fine," concludes Sir Martin Conway, "no part of the Alps now forms a better training-ground for the youthful would-be mountaineer, none a less vulgarised holiday resort for the man of moderate physical capabilities, simple tastes, or restricted means, than the region comprised in the Austrian and Bavarian Tyrol."

In *Scribner* there is also an article on scientific taxidermy, under the title "A Lost Art," by Mr. J. Carter Beard. The reform in taxidermic methods is said to have begun fifteen years ago. As instances of successful work are cited Mr. W. T. Hornaday's "Fight in the Tree-Tops," illustrating a characteristic episode in the lives of orang-utans, whose habits he had studied in their native forests, and whose skins and skeletons he had himself collected; Mr. Hornaday's group of flamingoes, and groups of bison, in the U.S. National Museum, and New York Museum of Natural History; a group of Rocky Mountain goats, by Prof. L. L. Dyche; a young camel, by Mr. Rowley, in the latter Museum, and the rehabilitation of "Chico," a large ape, done for the same museum by the same taxidermist. Nothing is said of any of the specimens in our own Natural History Museum.

The *Geographical Journal* contains the address delivered by Sir Clements Markham at the recent anniversary meeting of the Royal Geographical Society. There are also contributions on "The Pamirs and the Source of the Oxus," by the Right Hon. George N. Curzon; "Admiralty Surveys during the Year 1895"; "The Indian Surveys 1894–95," by Mr. C. E. D. Black; and "Geography at the Universities." In the *Contemporary*, Mr. A. E. Pease has a short article on the political geography of "Africa North of the Equator." The *Century* contains "Glimpses of Venezuela and Guiana," by Mr. W. N. King; a short paper on Eskimo life, entitled "An Arctic Studio (77° 44′ N. lat.)," by F. W. Stokes; and "Impressions of South Africa," by Mr. James Bryce.

A passing mention must suffice for the remaining articles of scientific interest in the magazines and reviews received. Under the title "Stray Thoughts on South Africa," Olive Schreiner contributes to the *Fortnightly* some facts as to the crossing of races in South Africa and the results of the mixture of blood; Prof. Max Müller's paper on "Coincidences," read before the Royal Society of Literature in May last, appears in the same review. Dr. Louis Robinson discusses, in the *National*, some aspects of "The Science of Change of Air," and offers a few sensible and seasonable suggestions on the subject. Mr. F. E. Hewitt has in the *Westminster Review* a historical study entitled "How the First Priests, the long-haired Shamans, and their successors, the Tonsured Barber-Surgeons, measured Time." To *Longman's Magazine* Mr. Grant Allen contributes a popular paper on "Lobsters at Home." Mr. James Buckland describes in the *English Illustrated Magazine* the remarkable mode of nidification of the hornbills, and makes a conjecture why the male bird plasters up the nest and keeps the female a prisoner until the eggs are hatched. Finally, *Chambers's Journal* contains its usual complement of instructive articles, among the subjects being Mr. Carey Lea's work on modifications of silver, and artificial perfumes of flowers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An examination in natural science (chemistry and physics) will be held on Wednesday, October 7, for the purpose of filling up a Bristol scholarship (open *pro hac vice*) of the annual value of £100 and tenable (under the usual conditions) for five years; the successful candidate to commence residence immediately upon election.

DR. T. M. LEGG has been appointed Professor of Hygiene in Bedford College, London.

THE widow of the late Dr. Arthur Jackson, of Sheffield, has presented £5000 to the Sheffield School of Medicine to endow a chair of Anatomy, to be named after her late husband.

THE Council of University College, London, have instituted a new Professorship of Pathological Chemistry, and have appointed Dr. Vaughan Harley to the professorship.

THE Cornell University has issued, in the form of a slender *brochure*, its programme of courses of instruction in physics for the session 1896–97. The Department of Physics occupies a large building known as Franklin Hall, and the equipment is valued at 50,000 dols. Prof. E L. Nichols has the services of an efficient staff, consisting of three assistant professors and seven instructors. The curriculum includes elementary courses for senior and junior students, advanced work both for undergraduates and graduates, and courses given in the summer school from July 6 to August 16. Among other encouragements for research, one university fellowship and one graduate scholarship in physics are awarded each year. With a view to affording still further stimulus for research, the University, three years ago, founded the *Physical Review*, which is the only journal in America devoted exclusively to physics. Such enterprise furnishes an example which our older English universities would do well to emulate.

THE Duke of Bedford has placed at the disposal of the Technical Instruction Committee of the Bedfordshire County Council a farm of 275 acres, 149 of which are arable land and the rest grass. In addition to this his Grace has erected the necessary lecture-rooms, dormitories, and other buildings for the accommodation of twenty students. Twenty boys are granted free scholarships by the County Council, entitling them to two years' board, residence, and instruction in the science and practice of farming. On Tuesday, June 30, the members of the Bedfordshire County Council were able, at the invitation of the Duke, to pay a visit of inspection to the farm, and are able to report that every branch of farm and garden practice is efficiently taught by means of models and specimens in school and of actual work on the farm, in the dairy, poultry-yard, and garden. The institution is modelled on the lines of similar school farms on the continent, which were inspected and reported upon by the Organising Secretary of Technical Instruction some time ago.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 4.—"On the unknown Lines observed in the Spectra of certain Minerals." By J. Norman Lockyer, C.B., F.R.S.

In the first note of the series "On the New Gases obtained from Uraninite," by the distillation method, the author remarked[1] "I have already obtained evidence that the method I have indicated may ultimately provide us with other new gases, the lines of which are also associated with those of the chromosphere."

In a subsequent paper "On the Gases obtained from the Mineral Eliasite," he gave a list of several unknown lines, and suggested that they might indicate the existence of a new gas or gases in that mineral, and added[2] "Although the evidence in favour of a new gas is already very strong, no final verdict can be given until the spectra of all the known gases, including argon, have been photographed at atmospheric pressure, and the lines tabulated. This part of the inquiry is well in hand."

The inquiry above referred to has now been completed and in the following manner:—

Photographs were taken of the spectra at atmospheric pressure of nitrogen, oxygen chlorine, carbonic anhydride, coal gas, sulphuric anhydride, phosphoretted hydrogen, and argon, these being the gases which, from the experience thus far acquired are likely to be associated with those given off by minerals. In addition to these the lines of mercury, potassium, and platinum, were also photographed. The lines of platinum are always present in the spectra for the reason that the spark is passed between platinum poles, while the lines of mercury or potassium frequently appear according as the gases are collected over mercury or potash.

For the wave-lengths thus obtained no greater accuracy than one indicated by four figures is claimed. It was the author's intention, in the first instance, to give five figures from the more elaborate tables of some of the elements given by other observers, but this had to be abandoned in consequence of the considerable variations found in the tables between the results as given by different observers.

A list is given of sixty lines which have been observed and photographed in the spectrum of the gases from eliasite which do not appear in the spectra of the old gases.

The author also gives a complete list of the unknown lines so far as the observations have at present gone, indicating their mineral origins, and whether or not lines nearly coincident in position have been observed in any celestial body.

This table includes about a hundred lines, a large number of which have celestial coincidences.

June 18.—"Complete Freezing-point Curves of Alloys containing Silver or Copper and another Metal." By C. T. Heycock and F. H. Neville.

From a study of dilute solutions of metals in copper, the authors arrive at 50 calories as a probable value for the latent heat of fusion of copper. The freezing-point curve of alloys containing silver and copper does not indicate the existence of any chemical compounds of these metals; but the eutectic alloy has exactly the composition Ag_3Cu_2. Lead copper alloys have a freezing-point curve characteristic of substances which are partially soluble in each other. The tin copper curve is remarkable for a singularity near $SnCu_6$, and another at exactly $SnCu_4$. The compound $SnCu_3$ is not clearly indicated in the curve.

For alloys whose composition is between $SnCu_6$ and $SnCu_4$, the freezing-point curve is perfectly straight, a feature that may be due to the separation of isomorphous mixtures of these bodies. Nickel and iron raise the freezing-point of copper, whilst gold and silver depress it.

Geological Society, June 24.—Dr. Henry Hicks, F.R.S., President, in the chair.—The President referred to the death of Sir Joseph Prestwich, and a resolution was passed assuring Lady Prestwich of the Society's heartfelt sympathy with her in the sad and irreparable loss that she has sustained.—Sir William Dawson, F.R.S., exhibited specimens and lantern-slides illustrating the general form, arrangement of laminæ, and distribution of the canals and tubuli in characteristic specimens of *Eozoon canadense*. He pointed out that an examination of these specimens and photographs might prevent mistakes likely to arise from the study of imperfect specimens, or from supposing that laminated rocks resembled *Eozoon*, and also that they exhibited additional peculiarities observed since the original publication of the description of *Eozoon* in the *Quarterly Journal* of the Society in 1865. He did not wish to enter upon any argument as to the nature of *Eozoon*, but merely to show the appearance of the principal structures on which the conclusion that it was of animal origin had been based. He also pointed out that these structures might be misunderstood when studied in imperfectly-preserved specimens, and that the wonder was not that so many specimens were imperfect, but that any structure had been preserved. He also shortly noticed the growing probabilities in favour of the existence of a rich marine fauna in pre-Cambrian times, and some of the discoveries in this direction already made or in progress.—Notes on the glacial geology of Arctic Europe and its islands. Part II. Arctic Norway, Russian Lapland, Novaya Zemlya, and Spitzbergen, by Col. H. W. Feilden; with an appendix by Prof. T. G. Bonney, F.R.S. The author gave an account of observations made in Arctic Norway, which tended to prove that the shell-bearing terraces were true marine deposits indicating uplift since their formation, and that they were not formed by ice-dams. He then described terraces recently formed in Kolguev Island, which illustrated the combined influence of pack-ice, sea-waves, and snow on the formation of terraces in a rising area. The glacial geology of the Kola Peninsula was next considered, and the distribution of the boulders noticed. There was no doubt that these boulders had been derived from local rocks, and that no ice-sheet from the North ever passed through Barents Sea or impinged on the northern coast of Europe. The author saw no evidence of the former extension of an ice-sheet over the now frost-riven rocks of Novaya Zemlya. He found wide-spread deposits of boulder-clay with marine shells in this region, which he attributed to the action of floating ice. In the Kostin Schar many of the islands were connected by ridges covered with rounded stones pushed up by floe-ice, with solid rock beneath glaciated by the floe-ice. Several minor phenomena connected with the glacial geology of Novaya Zemlya were also described. The raised beaches of Franz Josef Land were noticed, and immense deposits occurring in Spitzbergen, which were originally formed under water in front of glaciers, alluded to. These, as well as other submarine deposits of glacio-marine origin seen elsewhere by the author, showed no signs of stratification. Prof. Bonney described specimens brought by Col. Feilden from Norway, the Kola Peninsula, and Novaya Zemlya. From an examination of the rocks obtained *in situ* in the latter region, Prof. Bonney confirmed Col. Feilden's suggestion that the Kolguev erratics may have come from Novaya Zemlya.—Extrusive and intrusive igneous rocks as products of magmatic differentiation, by Prof. J. P. Iddings. The author, after pointing out the propositions concerning differentiation of magmas, upon which he is in agreement with Prof. Brögger, discussed the points of difference, and described the relation of the igneous rocks at Electric Peak to all of those which took part in the great series of eruptions which occupied almost the whole Tertiary period, and spread themselves over a vast territory in Montana, Wyoming, and Idaho. The author enunciated the principle that in a region of eruptive activity the succession of eruptions in general commences with magmas representing a mean composition and ends with those of extreme composition.

Edinburgh.

Royal Society, July 6.—The Hon. Lord M'Laren in the chair.—An obituary notice of the late Prof. James D. Dana was read by Prof. Geikie.—Dr. R. H. Traquair, F.R.S., read a paper on fossil-fishes from the Lower Devonian (*Hunsrückschiefer*) of Gmünden, Germany. Two species were described of which the first, *Drepanaspis Gmündenensis*, though named and briefly described by Schlüter in 1887, has hitherto been very imperfectly known. It has a hard and bony carapace composed of many tuberculated bony plates, a tail covered with rhombic sculptured scales, a heterocercal caudal fin bordered above and below with strong fulcra, but so far as can be seen there is no dorsal. There are no pectoral appendages. The position of mouth and eyes is still undetermined. The fish belongs undoubtedly to the *Ostracodermi*, and will form the type of a new family, *Drepanaspidæ*, whose position seems to be not far from that of the *Pteraspidæ*. The other species, *Coccosteus angustus*, Traq., was described as new—the ventral carapace is rather narrow, and the median dorsal plate shows evidence of an elevated median crest.—In the absence of Prof. Tait, Prof. Crum Brown briefly indicated the nature of his paper, a further communication on the kinetic theory of gases.—Dr. A. Lockhart Gillespie made a preliminary communication on digestion in some carnivorous plants. He gave a short *résumé* of the different classes of carnivorous plants, noting that the chief characteristic of all of them was not the power of converting native proteids into albumoses and peptones, but the complexity of the apparatus devoted to that end. In many plants, perhaps in all plants, peptonising ferments were present, especially in the seedlings, by which native proteids were resolved into diffusible forms which could be utilised in their nutrition. Darwin and others had shown in the case of *Pinguicula* and *Drosera* that many nitrogenous substances caused the glands of these plants to secrete an actively digestive juice. The author had investigated the action of the individual lower proteids on them, and also some of the lower derivatives of proteid digestion. He found that *Pinguicula* grew faster if fed once a week with a small quantity of proto-albumose than if nothing were given it, while raw egg-albumin, deutero-albumose, and peptone rather retarded its growth, especially the last. In fact, peptone (pure peptone, free from albumoses) killed the part of the leaf to which it was applied, after a few hours, however small the quantity. This was probably due to over-feeding. Serum globulin was slowly absorbed. Fibrin, coloured with carmine after Grützner's method, was not digestible; but egg albumin, coagulated in a weak solution of carmine, was slowly digested, and the glands could be seen coloured by the ingested carmine. He gave notes of the different times taken to absorb these various substances. *Drosera rotundifolia* reacted in a similar manner to these bodies. Its behaviour towards urea, kreatinin, tyrosin, nucleic acid, glycogen, and asparagin, was also investigated. Of these, only urea and asparagin were absorbed. Crystals of kreatinin were dissolved, but in a few days the leaf dried and the kreatinin could be seen crystallised out again on its surface. Crystals of urea, if very small, were readily absorbed; but, if large, speedily killed the leaf. Large quantities of asparagin were absorbed without detriment to the leaf, but these experiments were still in an unfinished state. With regard to the aggregation of protoplasm, as described by Darwin, Gillespie found that a very good way of obtaining permanent records of the process was to place the whole plant in a solution of some proteid weakly coloured with methylene blue, the protoplasm taking on the stain while the plant

continued to live. Under these circumstances the small sessile glands of *Drosera* stained deeply, showing that they became active in the presence of proteid material. Plants similarly treated with gentian-violet stained red where the glands were active, violet where they were only reflexly stimulated. The paper was illustrated by a number of lantern-slides and microscopic preparations.—Dr. C. G. Knott gave a summary of two papers by Mr. J. C. Beattie. The first was on the relation between the Hall effect and thermo-electricity in bismuth and in various alloys. That there was a connection was established, but what the precise nature of that relation was could not be determined till more definite knowledge of the Hall effect in alloys and with different temperatures, was arrived at. The second paper was on the curves of magnetisation for films of iron, cobalt, and nickel. The films were deposited on platinised glass and oscillated in the magnetic field. The results agreed with those already obtained for these metals in a solid condition.

PARIS.

Academy of Sciences, July 6.—M. A. Cornu in the chair.—The Secretary announced that the Institute would be able to award the Jean Jacques Berger Prize in 1897; the prize will be at the disposal of the Academy of Sciences in 1899.—Remarks by M. Albert Goudry on presenting a work on Philosophical Palæontology.—General laws of uniform flow in channels of large section, by M. J. Boussinesq.—Researches on tungsten, by M. H. Moissan. The pure metal is readily obtained by the reduction of tungstic acid with carbon in the electric furnace. With a large excess of carbon the carbide CW_2 is formed, which, in the fused state, readily dissolves more carbon, graphite crystallising out on cooling. Pure tungsten can be readily filed and forged, it welds easily, has no action upon a magnetic needle, and has a melting point higher than chromium and molybdenum.—On the solubility of carbon in rhodium, iridium and palladium, by the same. These three metals dissolve carbon with ease at the temperature of the electric furnace, and give it on solidifying in the form of graphite. No combination to form a carbide appears to take place.—Physiological action of high frequency currents; practical means for their continuous production, by M. A. d'Arsonval. When animals are placed within a solenoid traversed by currents of high frequency, the respiratory changes go on more rapidly. This was shown very simply by measuring the loss of weight in a given time.—Therapeutic effects of high frequency currents, by M. A. d'Arsonval. Since these currents have been found to cause a large increase in the rate of production of carbon dioxide in the body, it was thought that the application of such currents might give relief in diseases such as diabetes, gout and rheumatism, in which the rate of combustion is reduced. In two cases of diabetes the treatment produced marked relief.—On five photographs of the region round η-Argus, by Mr. David Gill.—Verification of Van der Waals's law of corresponding states, by M. E. H. Amagat.—Mr. Christie was elected Corresponding Member in the Section of Astronomy, in the place of Mr. Hind.—On a new capillary theory, by M. Marcellin Langlois.—A sealed note, by M. D. Loiseau, was opened: On some properties of raffinose, serving to estimate this substance in sugars.—On ordinary differential equations of the first order, by M. A. Korkine.—On the local attractions observed in Eastern Europe, by M. Venukoff. An account of the deviation of the pendulum in the neighbourhood of mountains in Bulgaria and in the Crimea.—On the refraction and diffraction of the X-rays, by M. Gouy. For the substances examined, the index of refraction, if not exactly unity, differs from it by a quantity less than the errors of experiment (·000001). As regards diffraction, none could be established with certainty, and the wave-length must be smaller than ·005 μ, or 1/100 of the wave-length for green light.—Composition of pendular movements, by MM. Jean and Louis Lecarme.—Comparative experiments on the pitch of cylindrical tubes vibrating transversely, by M. C. Decharme.—Action of zinc on the photographic plate, by M. R. Colson. The action has been traced to the vapour of zinc; it is most energetic after the surface has been cleaned with emery paper, but falls off as the surface oxidises. The practical conclusion is drawn that metallic zinc should not be used in the construction of the camera or dark box.—Action of nitrogen peroxide upon antimony trichloride, by M. V. Thomas. There appears to be no true compound formed, but only a solution of the gas in the trichloride.—The effect of a high temperature upon some sulphides, by M. A. Mourlot. In the electric furnace the amorphous sulphides of lead, antimony, zinc and cadmium are converted into galena, stibine, wurtzite, and greenockite respectively. The antimony sulphide gave some metallic antimony, but no trace of a sub-sulphide.—On two isomers of anethol (propenylanisol), by M. C. Moureu.—Action of ethoxalyl chloride upon naphthalene in presence of aluminium chloride, by M. L. Rousset. Two naphthylglyoxylic acids are obtained, the oximes of which on distilling *in vacuo* give (α) and (β)-naphthonitriles.—On amorphous greenockite of Laurium, by M. Christomanos.—Experimental researches on the effects of intravenous injections of saline solutions. Determination of their value in therapeutics, by MM. Bosc and Vedel.—Cutaneous evaporation in the rabbit; action of pilocarpine, by M. Lecercle.—On some points in the histology of the muscles of the Cirrhipedes, by M. A. Gruvel.—On an accidental parasite in man, belonging to the order of the *Thysanoures*, by MM. Frêche and Beille.—Influence of the composition of the water of lakes upon the formation of sub-lacustrine ravines, by M. A. Delebecque.—On a new sounding machine; portable apparatus with steel wire, by M. E. Belloc.

CONTENTS.

THURSDAY, JULY 23, 1896.

GEOLOGY FOR STUDENTS.

The Student's Lyell; a Manual of Elementary Geology. Edited by John W. Judd, C.B., LL.D., F.R.S., Professor of Geology, and Dean of the Royal College of Science. 8vo. Pp. xxiv + 635. (London: John Murray, 1896.)

THERE are plants so deep-rooted in their native soil that time seems practically powerless to eradicate them, and even when razed to the ground, they will yet spring up again, from their tenacious hold in the heart of the earth beneath.

Thus it is with the teachings of Lyell; they have taken so strong a hold upon the minds of English geologists, that although the great historian of our science has been dead since 1875, yet his writings still illumine the path, and serve to guide full many a student who was unborn when Lyell died.

For the great "Principles of Geology," the inception of which takes us back to a far earlier period than the first edition of the "Student's Elements of Geology," indeed to more than sixty years ago, are still the guiding "principles" along which the great lines of geological thought continue to flow at the present day.

It is true that from 1858 Lyell became a thorough convert to the Darwinian theory of evolution, and, in the later editions of his works, he fully accepted the inevitable conclusions which these views involved; yet so far from weakening his hold on geological thought, the very openness of his mind proved him to be a teacher worthy to be followed and trusted, one who was able to accept new impressions and to advance, even in later life, along new lines of scientific thought.

In the work before us, we have embodied not only the survival of all that is best and fittest of Lyell's teachings, both in his "Elements" and "Principles," but also there has been superadded to the original work—by a species of "grafting" upon the parent Lyellian "stock"—a vigorous shoot from a new root—that of Prof. Judd, representing the later school of geology, as carried on in the Royal College of Science, South Kensington, formerly the Royal School of Mines, where, year after year, so many students have been trained to become geologists and to go forth to convert the wilderness into paying gold-fields, or to make geological maps of our colonies all over the world.

But much as this has added to the usefulness and up-to-dateness of the "Student's Lyell," we are reminded that other great "medicine-men" in geology have not hesitated to lend their aid to keep alive the school of Lyellian principles; and we may record that Profs. P. M. Duncan and T. G. Bonney, Mr. Etheridge, Prof. Rupert Jones, and Dr. W. F. Hume, have all helped to make this volume what it is to-day, a most useful and handy student's text-book of geology.

In spite of the expansion of the text, and the introduction into it of more than one hundred new illustrations, it has nevertheless been found possible, by using smaller type for certain portions, to avoid increasing the bulk or the cost of the volume.

Part i. embraces the introductory matter, such as the history of the development of geological science, the crust of the globe, and the nature of rocks and their classification.

The physical characters of the earth's crust, its chemical composition, and the distribution of temperature within the crust, has been entirely rewritten so as to embrace the latest information obtained by the most modern investigations.

The general relations of the stratified rocks, dealing also with the composition and classification of aqueous deposits in general, occupy the next hundred pages.

The following chapters treat of the chronology of the aqueous rocks, commencing with the Tertiary—these are disposed of in five chapters; the Secondary rocks occupy four more chapters, the Newer Palæozoic take fifty-eight pages, and the Older Palæozoic era is condensed into forty-one pages.

In dealing with the great series of aqueous or sedimentary rocks, more than five hundred figures of characteristic fossils are introduced into the text, and everywhere the importance of palæontological evidence as a means of determining the age of the rocks under consideration is pointed out; also the value of fossils as showing the earliest appearance in time of the various groups of living organisms is fully demonstrated.

Chapter xxix. gives us a general review of the sedimentary rocks; and here the student is made to understand that, as in the history of the human race, so it is with the history of the earth. In each case the later chapters are very fully and well preserved, and easily read and understood; but in both, the earlier portions become more and more fragmentary—often whole chapters are missing, and those which remain are frequently torn and mutilated.

"If we bear in mind how small must be the proportion of the relics of plants and animals now existing, that have any chance of being buried and preserved in the accumulations now being formed in seas and lakes; if we consider how remarkable must be the combination of circumstances conducing to the mineralisation of those relics, and their preservation to a remote antiquity; and if we reflect upon the remoteness of the probability of organisms, when buried and preserved by fossilisation, being exposed at the surface and found by man—we shall be on our guard against regarding the thousands and hundreds of thousands of beautiful fossils which are displayed in our museums, as representing more than a very small fraction indeed of the forms of life that have once existed on the globe" (pp. 442).

Part iii. deals with volcanic phenomena and products, with plutonic and metamorphic rocks, veins and metalliferous deposits. With this part of the work Prof. Judd must have felt, perhaps, the deepest interest, having made a special study for years of the volcanic phenomena of Europe, and given us in his volume on "Volcanoes" an excellent *vade mecum* which every student must possess.

It is interesting to know what line of thought Prof. Judd follows in reference to the assumed permanence of oceanic and continental areas; as this subject has greatly disturbed the minds of geologists of late years.

"From all that we know of the extreme slowness of the upward and downward movements which bring about even slight geographical changes, we may infer that it

would require a great lapse of time to cause the submarine and supramarine areas to change places, even if the ascending movements in the one region and the descending in the other were continuously in one direction. But we have only to appeal to the structure of the Alps, where there are so many shallow and deep-water formations of various ages crowded into a limited area, to convince ourselves that mountain-chains are the result of great oscillations of level. High land is not produced simply by uniform upheaval, but by a predominance of elevatory over subsiding movements. Where the ocean is extremely deep it is because the sinking of the bottom has been in excess, in spite of interruptions by upheaval" (p. 124). "Movements of 1000 feet or more would turn much land into sea, and sea into land, in the continental areas and their borders; whereas oscillations of equal magnitude would have no corresponding effect in the bed of the ocean generally, believed as it is to have a mean depth of nearly 13,000 feet. The greatest depths of the sea do not exceed the greatest heights of the land; it may, therefore, seem strange that the mean depth of the sea should exceed the mean height of the land six times, even taking the lowest estimate of the ocean depths as given by the late deep-sea soundings. This apparent anomaly arises from the fact that the extreme heights of the land are exceptional and confined to a small part of its surface; while the ocean maintains its great depth over enormous areas. It is evident that, during the recent periods of the earth's history, there have been great subsidences and elevations of the land; many raised beaches are 1000 to 1200 feet above sea-level. Dana, following Darwin's theory of atoll formation, terms the atoll a memorial of a departed land, and considers that the great Pacific subsidence was contemporaneous with the post-glacial upheaval in the north" (p. 123).

The volume concludes with three brief appendices, giving (*a*) a useful account of the common rock-forming minerals, (*b*) a classification of plants, and (*c*) of animals, both living and fossil.

The name of each mineral is conveniently printed in blacker type than the rest of the text, so as more readily to catch the eye. The names of the extinct orders of plants and animals are similarly printed in blacker type.

In appendix (*c*) there are a few errata, which should be corrected in a future edition. For instance, the worms of various kinds appear under two headings; nine orders being arranged in Series V. (p. 609), under Annuloidea, and four other orders have crept into Series VIII. under Arthropoda (on p. 610). On the same page "May-flies" are given as an example of Orthoptera instead of *Blatta* or *Mantis*. The Phyllocarida (represented by *Nebalia*, *Ceratiocaris*, &c.) have been accidentally omitted; also Schizopoda and Cumacea.

In the Reptilia, Proterosauria and Procolophonia are left out; and for Orthopoda, we would suggest Ornithopoda (bird-footed) as more correct. For Odontornæ (p. 612) read Odontormæ. Under Mollusca (on p. 609), by using the terms Gastropoda and Pulmonata, the student is in danger of supposing that snails are not gasteropods, whereas the Pulmonata are only a *subdivision* of the Gasteropoda.

We have only referred to this last appendix because it is stated (on p. 612) that the classification followed is that of Huxley, E. T. Newton, and Zittel; but no one would for a moment wish these authors to be held responsible for misprints which have accidentally crept into the table in its present form.

It is to be regretted that the classification of the fishes followed by Prof. Judd, is that of Prof. Zittel, which is now considerably modified by the later arrangement (1896) of Mr. Arthur Smith Woodward. In this latest work we find that *Pteraspis*, *Cephalaspis*, *Pterichthys*, &c., are placed in a distinct division of armoured notochordal animals, the Ostracodermi; while the old division Placodermi, is broken up; the Arthrodira (*Coccosteus-like*-fishes) alone remaining. In a similar manner the Actinopterygian order has replaced the old order Ganoidei, which has disappeared.

We have already spoken in commendation of the great abundance and excellence of the illustrations (more than 700 in number) which adorn the present work; we may, however, venture to take exception to the figures of *Cephalaspis Lyelli* (p. 380) and of *Pterichthys* (p. 382). Page's figure should be replaced by the careful restoration by Prof. Ray Lankester, and Hugh Miller's *Pterichthys* by Dr. R. H. Traquair's elegant and accurate figures of that remarkable genus.

Time and space alike preclude us from doing fuller justice to this excellent text-book; but we feel assured it will live on and be read not only by many geological students, but by a large section of the English public who still hold the name of Lyell in high estimation and value his teachings. Thus will this little volume serve to keep alive the memory of one who was, perhaps, the greatest geological writer and expositor of this century.

BOULENGER'S CATALOGUE OF SNAKES.

Catalogue of the Snakes in the British Museum (Natural History). Vol. III. Containing the Colubridæ (Opisthoglyphæ and Proteroglyphæ), Amblycephalidæ, and Viperidæ. By George Albert Boulenger, F.R.S. Pp. xiv + 727, 25 plates. (London: Printed by Order of the Trustees, 1896.)

WITH the issue of the present volume Mr. Boulenger completes his examination and description of the herpetological collections in the British Museum, which have occupied his attention for more than fourteen years. The whole series of Catalogues thus brought to a conclusion consists of nine volumes. Two of these, issued in 1882, are devoted to the Batrachians, with the study of which Mr. Boulenger commenced his labours in our National Museum, three to the Lizards (1885–87), one to the Rhynchocephalians, Chelonians, and Crocodiles (1889), and finally three to the Snakes. The enormous series which has thus been examined, classified, and catalogued consists of 38,086 specimens. These have been referred by Mr. Boulenger to 3905 species, while 1265 others, which are allowed by the author to be valid, but are not represented in the British Museum, raise the total number of known species of Batrachians and Reptiles to 5170. While it is thus evident that our great National Institution is not without its deficiencies, there can be no doubt whatever that as regards its herpetological collections, when compared with similar institutions on the continent and elsewhere, it stands absolutely unrivalled. The collection of Reptiles and Batrachians at South Kensington is "not only the largest but also the best arranged in existence, every specimen of it having been carefully examined and classified according to a modern

system after consultation of the whole literature of the subject." Moreover, the so-called "Catalogues" are not mere lists of specimens, but, as we are assured by the Director in his preface to the last volume of the series, are "complete monographs of the groups of animals treated of, so far as their zoological characters, geographical distribution and synonymy are concerned, descriptions being given of every species regarded by the author as valid, whether represented in the Museum or not." It is not too much to say that no more arduous or more important piece of zoological work has been brought to a successful issue, in modern days, than that which has been thus accomplished by the unremitting devotion of the author of these Catalogues to his task during the past fifteen years.

With regard to the Ophidians or Snakes, which are more immediately the subject of the present notice, Mr. Boulenger has had a specially difficult subject to deal with. Next to the Lizards the Snakes are the most numerous Order of Reptiles. But while the Lizards present many well-marked characters for their division into subordinate sections, the great mass of Snakes belong essentially to one extensive group which Mr. Boulenger allows only to rank as a family. Out of the whole number of 1639 species of Snakes recognised as valid in the present work, upwards of 1250 species are referred to the Colubridæ. The proper treatment of this family is one of the most embarrassing questions for the Herpetologist. The formerly recognised division of Snakes into Venomous and Non-venomous is altogether discarded by the author, who takes the structure of the skull and other anatomical characters as his guide. The great family Colubridæ embraces venomous as well as innocuous species; indeed, the poison of some of the Proteroglyphous Colubrines (such as the Cobras and Hydrophids) is quite as deadly as that of the Vipers and Rattlesnakes. In another work, recently published, Mr. Boulenger has spoken as follows upon this subject :—

"A general desire is felt by those not well acquainted with Snakes to be able to distinguish at a glance between harmless and poisonous forms. To meet this requirement various criteria have been proposed, none of which, however, are satisfactory. It is well to state at once that there is no sure method of distinguishing the two forms by external characters, except of course a knowledge of the various forms. And even then a cursory examination is not always sufficient, since there is, in some cases, a striking resemblance between Snakes of totally different affinities, by which even specialists may be at first deceived. In short, nothing but an examination of the dentition can afford positive information as to the poisonous or non-poisonous nature of an unknown Snake."

Mr. Boulenger divides the Ophidians as a whole into nine families. He commences his systematic arrangement with the small worm-like Typhlopidæ, which pass their lives in burrows beneath the earth. They are numerous under the tropics, upwards of 100 species being already known, and many more in all probability awaiting discovery. The allied family Glauconiidæ, of which twenty-nine species are registered, has similar habits. Next to these come the Boas and Pythons (Boidæ) with sixty-six species, amongst which are the monsters of the Ophidian Order. *Python reticulatus*, of the Malay countries, is said to attain a length of thirty feet, and the Anaconda of tropical forests of South America to arrive at still larger dimensions. Of the small family Ilysiidæ, which is intermediate between the Boas and the Earth-snakes (Uropeltidæ) only five species, belonging to three genera, are known, two of these being East Indian, while one, strange to say, is South American. The Uropeltidæ, on the other hand, offer us an example of an extremely limited distribution, the whole of the forty-two known species being restricted to the mountains of Ceylon and the Indian peninsula, where they are frequently dug up in the plantations of Tea and Coffee. The sixth family of Snakes, according to Mr. Boulenger's system, consists only of the anomalous *Xenopeltis unicolor*, of India and the Malayan countries, while the seventh family, the Colubridæ, as we have already mentioned, is by far the most numerous of all, containing, in fact, more than three-fourths of all the known species of Ophidians. Mr. Boulenger divides this enormous "family" into "three parallel series"—Aglypha, Opisthoglypha, and Proteroglypha. The first of these, with solid teeth, are harmless; the last, with the anterior maxillary teeth grooved or perforated, are venomous; while the Opisthoglyphs, with the posterior maxillary teeth grooved, are all to be suspected, and usually more or less poisonous. The highly venomous Proteroglyphs are followed, although they do not lead into the typical venomous Serpents with erectile maxillary, which Mr. Boulenger unites into one family—Viperidæ—classing the Pit-vipers and Rattlesnakes only as a distinct sub-family. This is his ninth and last group of Ophidians. Between it and the Colubridæ, he locates as an eighth family the Amblycephalidæ, the members of which have but little power of expanding the mouth, and feed on insects and other small prey. Of Amblycephalidæ, thirty-four species are characterised and referred to five genera.

Whatever objections may hereafter be taken, and in some cases perhaps maintained, against Mr. Boulenger's rather revolutionary scheme of the classification of Snakes, there can be no question that his "Catalogue" makes a most distinct and remarkable advance in our knowledge of these animals, and will in future be employed by herpetologists all over the world for the arrangement of their collections, and as a solid base for future research. In the case of the "Catalogue of Birds," now nearly brought to a completion in the same zoological workshop, it has been found necessary to employ many different authors whose discordant views result in a somewhat incongruous whole. But herpetology has been more fortunate than ornithology in finding a naturalist of conspicuous ability and untiring patience who has achieved the feat of arranging and classifying all the subjects under his charge upon a uniform system.

THE MANAGEMENT OF PUBLIC WORKS IN THE UNITED STATES.

The United States Public Works Guide and Register. By Captain W. M. Black. Pp. vi + 276. (New York: Wiley and Sons. London: Chapman and Hall, 1895.)

THE public works of the United States are in charge of officers working under different bureaus of the executive departments of the Government. All harbour,

river, and dock works are carried out by the Government; the department charged with this work being under the command of a chief engineer, who, with a small staff, has his headquarters at the seat of Government; the other officers of the corps being stationed throughout the country wherever their presence is required. In the same way the lighthouses, buoys, and sea marks are under the charge of a Government department, the chief of which is the Secretary of the Treasury; the other members of the Board consisting of two officers of the Navy, two of the Corps of Engineers of the Army, two civilians of scientific attainments, with an officer of the Army and one of the Navy as secretaries. The coast is divided into districts, each under the charge of an engineer. All works in connection with fortifications and defences and military engineering are managed by the department of the Secretary of War. The quartermaster's department takes charge of all stores, transport, and military buildings; and another officer of the War department has charge of all public buildings and parks.

For the guidance of the officers of these several departments a code of regulations is drawn up as to the management and conduct of contracts, and of works performed by the department. This code provides that "the importation and migration of foreigners and aliens under contract or agreement to perform labour in the United States is forbidden." That, except in cases of extraordinary emergency, the services of labourers and mechanics employed on any public works are limited to eight hours in the day. Legal holidays for employés of the Government are January 1, February 22, July 4, and December 25. Day-workmen are paid for these days, and for such other days as may be designated days for national thanksgiving by the President. The first Monday in September, known as "Labors Holiday," is a legal holiday. In the case of contracts, all persons tendering are to be notified of the time when the tenders are to be opened, and may be present, either in person or by their agents. Any officer or agent of the Government, or any member of Congress, who receives money or other bribe in connection with any contract or work, is deemed guilty of misdemeanor, and is liable to imprisonment for a period not exceeding two years, and to be fined a sum not exceeding 10,000 dollars.

The design of Captain Black's book is to show the prescribed business methods of those of the executive departments which principally control the Government work, and to describe the nature of the works and the plant and materials most frequently required. The general laws and regulations under which all the public works are carried on are given; also a description of the departments, and of the works executed by them. Engineering principles are not dealt with, but there are numerous descriptions of works, with their cost, and illustrations of the plant used, and the method of carrying them out. These include fortifications, sea and lake shore protection works, river training works, lighthouses, public buildings, &c.

It is the practice of the Works Department of the Corps of Engineers to issue annually full reports of all works going on in the several departments. These reports are often fully illustrated, and contain numerous details as to contracts entered into, cost of the work, and results attained. Any one who is familiar with these, will at once recognise that the contents of the book are largely taken from them. This, however, in no way detracts from its value.

Although the book is written for and would be of great service to engineers in the United States, it yet contains a great deal of information respecting the works carried out in that country in training and improving rivers; and the various methods of dredging in use and the cost, and also as to the works for lighting the coast, which would be found useful and instructive to English engineers. "Suction" dredging has been much more largely used in the United States than in this country, whether as applied to the removal of sand or of clay and harder material. The methods used for disintegrating hard material, and either pumping it up by centrifugal pumps or pulsometers, or by a vacuum chamber, is fully described. In the latter case, steam is admitted to a cylinder or vacuum chamber, then condensed with cold water, the vacuum formed causing an inrush of the materials to be raised through a suction-pipe; this material is then driven out through the discharge-pipe by the admission of the steam. As an illustration of the nature of the materials this method of dredging is capable of dealing with, it is stated that a 1300 lb. stone was picked up and forced through the pipes on one occasion, and on another an iron safe measuring 25 inches by 16 inches by 14 inches.

OUR BOOK SHELF.

Wild Life of Scotland. By J. H. Crawford, F.L.S. Pp. 280. (London: John Macqueen, 1896.)

Pastoral life has charms for a large proportion of the reading public, if one may judge from the quantity of literature dealing with its scenes and events. Perhaps the strain under which men now work in cities, has resulted in a reaction in favour of a return to nature. Certain it is that there is a demand for simple papers on subjects of outdoor natural history; and though much of the supply to meet is not above criticism, still the taste for descriptions of rural scenes and wild nature is well worth cultivation. Mr. Crawford has a passion for wild nature. He would like to rehabilitate some of the isolated hills and woodlands of Scotland with the reindeer, beaver, and wild boar; but the general opinion of his correspondents appears to be: "We cannot afford to grow wood for beavers to gnaw, or for boars to whet their tusks on." To see nature at her best in Scotland, he has gone away beyond enclosures, and has observed and judged of her ways for himself. This collection of papers, which represent the result of his observations and meditations, are typical of the forms of life in the woods and waters of Scotland; they are pleasantly written and attractively illustrated, and will interest all country naturalists.

A Cosmographical Review of the Universal Law of the Affinities of Atoms. By James Henry Loader. Pp. 93. (London: Chapman and Hall, Ltd., 1896.)

It is a little difficult to understand the theory presented in this book. To do justice to the author, and at the same time enable readers of Nature to appraise the contents at their proper value, we give a few extracts. It is stated that men of science have concluded "that all space must be composed of an element extremely rarefied, and that element they denominate ether." Having accepted this opinion himself, the author infers that the ether is "the primary essence of all matter, whether in a gaseous

liquid, or concrete form," which inference leads to a conclusion that seems to contain the gist of the theory advanced, and is expressed as follows. "Therefore it is reasonable to assume that this ether is composed of atoms in their normal and most rarefied state, distinct and varied in species as to their nature and substance, are unchangeable and undestructible, involved by forces of affinity from ether to a density (*sic*), and finally into a gaseous, liquid, or concrete form. And as all matter known to us is capable of being rendered volatile, either by the action of heat or potent dissolving alkalies, they are dissolved again in the course of eternity from concrete to ether." The author applies this principle of "Ether thou art, and to ether shalt thou return," very comprehensively, taking in such diverse subjects as "Nebulæ resulting in Solar Formations," "The Phenomena of the Magnet and Aurora Borealis," "The Survival of the Fittest in Protoplasmic Organisms," "Mind of Mankind," and "Rise and Fall of Nations." He also discourses freely upon "free calorics" and "latent calorics," which apparently play an important part in the scheme of involution and devolution set forth.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Position of Science at Oxford.

MAY I be allowed, as one who has had some experience both within the University itself, in more than one capacity, and also in one of our public schools, to offer a few remarks on this subject?

Your recent article states that the failure of the Science School at Oxford is not complete because "it has long been recognised that the attainments of the limited number of scientific men which it turns out compare well with those of men who have been educated in other places"; while in a subsequent passage we read: "The Science School at Cambridge has acquired such a prestige that the best boys go there, and only the second best to Oxford." These two statements are either mutually opposed, or the teaching at Oxford is of so high an order that while there the "second best" are made capable of favourable comparison with those "best boys" educated elsewhere "Failure" is hardly an apt description of such an achievement. In my opinion Oxford gets its full share of "best boys." I can quote instances of boys of second-rate ability who have gained scholarships at Cambridge, but would have failed to do so at any college at Oxford. The standard required by Oxford is undoubtedly a higher one than that which is sufficient at many (not all) Cambridge colleges; and, as a rule, the value of Oxford scholarships is correspondingly greater In my experience the character of the Final Honour Schools of Science at Oxford is such that a boy of brilliant attainments and originality is more benefited by the course there prescribed, than by the wider but shallower training of Part I. of the Science Tripos. It is my practice to endeavour to send such boys to Oxford, and hitherto there has been no cause for repentance. The prestige of the Cambridge Medical School is undoubtedly a great obstacle to the increase in numbers (if indeed this is to be desired) of science students at Oxford. London and Cambridge practitioners far outnumber all others, and it is to one of these that the parents of boys who give evidence of scientific tastes, turn for advice regarding their sons. Can it be wondered that the advice given is generally in favour of some school other than at Oxford? Until the general public realises that, alike in pure science and in medicine and surgery, Oxford can and does hold her own with other places of education, the number of Oxford students will remain small.

I believe, however, that many staunch friends of Oxford hold with me, that a small school of high standard is more in accordance with her best interests, than a large one in which applied science stifles the acquirement of knowledge for its own sake.

You pronounce, on the whole, against Greek as a compulsory subject. Does any scientific man who has learnt, be it never so little, Greek, regret the time spent upon it? In teaching elementary science, especially biology, it is brought home to the teacher that technical terms form a serious stumbling-block to many boys; but if the classical derivation of these words is mentioned, they at once cease to be difficulties, and become readily familiar. The Greek language is called into service in so many of these modern terms, that ignorance of Greek cannot fail to materially increase the obstacles that beset the path of the beginner. This is perhaps a low ground on which to argue in favour of Greek, but it is one that is too frequently entirely overlooked by its opponents.

"On the whole, the teaching in public schools is bad." One of the accused can hardly reply impartially to such a charge, but I fully agree with the half-acquittal implied in the subsequent query: "Are the public schools altogether to blame?" Science labours under heavy disadvantages at most public schools. The *genius* of the schools is classical. The value attached to science is so small, that even a promising boy cannot make up by his science for deficiency in classics or mathematics, and thus is condemned to pass his days in the lower part of the school; whereas the acute classic, however obtuse in science, is in no way hindered on his path to the sixth form. Promotion is on the aggregate of marks, and the proportion allotted to science is insignificant. Classes are arranged by aggregate merit, and a graduated series of science classes grouped according to scientific ability is almost unknown. A scientific subject added to responsions would probably improve matters; but it must be remembered that some minds are so constituted (I speak from experience and mature conviction), that scientific subjects are to them of no educational value whatever, and a compulsory examination in science would prove an impediment to many a brilliant classic whose progress we should do ill to bar. If, however, such an examination were to act in a downward direction, and cause public schools to include science in their entrance and scholarship examinations, it would indeed serve a good purpose. Few preparatory schools include science in their curriculum; their whole energy is devoted to those subjects which will bring a substantial return of advertising value in the form of a scholarship. Experience has shown me in an unmistakable way that boys who have gone through the entrance scholarship mill have, in most cases, had all aptitude for science crushed out of them, and that they require a course of mentally-invalid treatment before any of them recover a healthy tone and attitude of mind towards a subject of which they have been hitherto kept in ignorance These boys are presumably the pick of their contemporaries in general ability, and at present these keener intellects are debarred from exercise in scientific subjects, for which assuredly some few would exhibit a preference.

In a guarded expression you give your vote to the study of physics and chemistry in schools. This view is one very generally held; but I believe it to be wrong, and an inversion of the natural order. Our object, I take it, is to draw out and develop in our pupils those talents that they severally possess. Boys are outdoor beings, and they should be so; nearly every boy at some period of his life collects insects, bird's eggs, or flowers. It is this collecting instinct which ought to be converted by education into the observing habit, and so made a natural foundation on which to erect a truly scientific superstructure of acquired knowledge. More boys are interested and intellectually stimulated by subjects touching on natural history than by physics and chemistry. These last not infrequently repel at first, whereas the others can to a certain extent be pursued on the play-fields and in the surrounding country. The pupil soon finds that he must acquire some knowledge of physics and chemistry; and the want being felt, the task is more willingly undertaken. In this connection I must state my belief that the present style of examination for science scholarships at both Universities does not give sufficient opportunity to the "boy naturalist," and indeed the majority of boys who become scholars are not "naturalists" in any sense Many colleges have in this respect materially improved their examinations recently, and the change is beginning to bear fruit; but until it is more widely recognised that the boy naturalist is the parent of the man scientific, so long will many minds, by nature best suited to extend our knowledge, be diverted into unnatural and less fertile channels. OSWALD H. LATTER.

Charterhouse, Godalming, July 13.

In your issue of July 9 there is an article on "The Position of Science at Oxford," and though I am not very well acquainted with that position, and am entirely in sympathy with the writer in his endeavour to get that University to encourage the science student more than it does, yet there are some remarks in the article to which I must take exception.

The statement that men of a year's standing at Cambridge, who come up with a moderate acquaintance of science, have an opportunity of bringing themselves up to scholarship standard at the end of their first year, sounds rather as if this was of importance in attracting the science student to Cambridge. But is this opportunity really of importance? Do many men in reality get scholarships in science at the end of their first year? Is not the scholarship money rather used in increasing the value of the scholarships already gained, than in forming new ones? Are not those who go up with "a fair general education and only a moderate acquaintance with science," more often advised by their college tutor to go in for the general examination than to specialise in science at once?

But after making the above statement, unsupported by statistics, the writer goes on to make an onslaught on science teaching at our public schools as the cause of the inferiority of the science student at Oxford.

Taken as a whole, he says the science teaching at our public schools is bad. The arguments he brings forward to support this statement are that, firstly, the inducements offered to learning science are very few; secondly, it is openly discouraged; and thirdly, boys neglect those studies which may safely be neglected. He seems to try, moreover, to prove the absence of good science teaching by the fact that the average boy comes up to the university destitute of scientific ideas. Let us take these points separately. The teaching is bad because the inducements to learning science are nil. This will be news to many who spend their lives in teaching science. What are the inducements to learn anything? At an early age two, at least, of the inducements to learn are interest and fear. Now the interest taken by the average boy in learning about the things around him—the earth, the air, plant or animal life—is undeniable, and it is far easier to get him interested in events which occur in the natural world than in G.C.M. or *Mensa*. While if fear is to be called on as an inducement, it is as easy to cane him for not doing his science work as it is to cane him for neglecting his classics. But later in life a boy begins to think of his future; and if he chooses a career in which a knowledge of science will help him, it will be just as great an inducement to work hard at science as it would be to work hard at classics if he had chosen a career in which classical learning was of importance. Still later he may learn to look at learning for its own sake, and he will feel that if he has a bent towards science, he will be able to educate himself by working hard at science, just as if he had a bent towards any other study he would be induced to work hard at that particular study. So that the statement that the inducements offered to the study of science are very few, is a somewhat extraordinary one to make.

Secondly, the statement that learning science is openly discouraged is, happily, becoming a false one. There are few of our public schools now that are not doing a great deal of science teaching; and though it is to be hoped that science teaching will spread still more, yet one must gladly acknowledge the enormous advance of science teaching during the past decade, and must feel that the open discouragement of science is now no longer in existence.

But what shall be said of the argument that the product of public school science teaching is a failure because boys neglect those studies which may safely be neglected? This is a direct attack on the science teachers at all our public schools as being inefficient teachers, and is an argument for calling on all headmasters to dismiss their present staff of science teachers. Before accepting this conclusion it would be of interest to know who your correspondent is, that one might know what sort of authority he speaks with, and what knowledge he has of the science teaching at the public schools. Moreover these schools, with their absence of inducements to learning science, and their absence of efficient teachers in that subject, send science scholars in large numbers to Cambridge.

But the final argument that science teaching at the public schools is bad, is because the average schoolboy comes up to "the University" destitute of scientific ideas. There is no clue to what he means by "the University"; but, taking Cambridge as an example, a considerable percentage of its undergraduates who go in for an honours degree, take up the Natural Science Tripos, a large number go in for medicine, and others go in for the study of science in order to get an ordinary degree. Most of these have done a considerable amount of science at school, and cannot be said to be destitute of scientific ideas. But many of the others, who go in for classics, mathematics, or other studies, although they may not remember the equation representing the action of sulphuric acid on chalk, yet, if they have been taught elementary science in their youth, may have learnt from it some of the accuracy and method which should characterise their work in any direction; while the training given to the mind in forcing it to appeal from written words or spoken statements to experimental facts is of immense importance, even though the particular facts may themselves be forgotten.

But the cry that Oxford is not attracting the science student in large numbers, is no doubt true; and the reason is to be sought inside, not outside, her walls. Cambridge, it is confessed, is not in the like predicament; and Cambridge has attracted many, who would not otherwise have gone to a university at all, by her medical and engineering schools.

A vast number of boys who do science at school, go straight to the hospitals or to technical institutions; and if Oxford is to attract the science student, she must develop that side of her teaching.

Cheltenham College.

Capture of a Specimen of "Lepidosiren" in the River Amazons.

I HAVE just received a letter from Dr. Émil Goeldi, Director of the rising Museum at Pará, in which he informs me of the interesting discovery of *Lepidosiren* at the mouth of the river Amazons (or rather of the river Tocantins). I had better give the part of his letter which refers to this capture. The letter is dated Pará, June 9.

"I have the pleasure of informing you of the discovery of *Lepidosiren* at the mouth of the river Amazons, viz. on the island Marajó. This afternoon I received, from a friend who has large possessions in the island, a specimen in spirits. The mail leaves in a few hours, so that I can scarcely do more than send you a few lines announcing this fortunate event.

"Often, since my arrival in Brazil, has my attention been directed to the search for this Dipnoan, especially by Prof. Karl Vogt and yourself. But it was only after my appointment to the Pará Museum, that I could take up the matter with a reasonable hope of success. I began with distributing thousands of copies of Natterer's figure in reduced size all over Amazonia, and sending paragraphs to the local newspapers in the interior. No local magistrate, no village schoolmaster escaped a notice.

"In consequence of this propaganda I received about a year ago a communication from Dr. Vicente Chermont de Miranda, who takes a great interest in all scientific matters; he informed me that the fish occurs in Marajó, and that he had seen already two specimens. The specimen sent to me now is therefore the third which has come under his notice. It measures, in the present state of preservation, about 58 cm., and is of a slate-colour. The ovaries are well developed, and show that the specimen was killed close to the spawning-time. No villi on the hind-limbs; vent asymmetrical, on the left side; greatest width of body 7 cm. Well acquainted with Ehlers's and Lankester's papers on *Lepidosiren paradoxa* and *articulata*, I looked immediately to the structure of the fin-cartilage. Its segmentation can be seen even without removing the skin, as figured in Lankester's memoir (Fig. 4). Therefore, our Amazons-specimen might be called *articulata* on the same ground as the Paraguay specimens collected by Bohls. But I agree with you and Prof. Lankester that there is one species only of *Lepidosiren*, viz. *L. paradoxa*—*L. dissimilis*, *gigliona*, *articulata* being synonyms.

"The exact locality for our specimen is Fazenda 'Dunas,' on Cape Magoary, Island of Marajó.

"One word more: Prof. Lankester speaks of five Amazons-specimens in European museums. I believe there are six. Only a few years ago the late Mr. Gustav Toepper obtained a specimen near Itaituba on the Tabajóz River which, as I have been credibly informed, has found its way into the Berlin Museum."

ALBERT GÜNTHER.

Eskimo Throwing-Sticks.

I SEND you herewith a drawing of a throwing-stick which was brought to Washington by Captain John Rodgers, U.S.N., of the *Vincennes*, who explored the Behring and the Arctic Seas from 1850–55.

In my paper on the "Throwing-Stick" (Rep. U.S. National Museum, 1884, pl. vi.), this is figured as the Rodgers specimen, locality unknown. Subsequently, M. Adrien de Mortillet produced in the *Revue Mensuelle de l'École d'Anthropologie* (viii. p. 246) a figure of a similar apparatus. Since then Mr. Walker Clark, of Edinburgh, Scotland, has sent me photographs of the same type from the Edinburgh Museum, and apparently associated with Beechey's explorations.

Dr. Franz Boas calls my attention to specimens of the same type in the American Museum in New York. The U.S. National Museum has also similar objects collected by Mr. Jas. G. Swan and the Rev. Vincent Colyer.

I have ascertained, by searching the records, that Captain Rodgers touched at Unalashka and collected specimens at that

place belonging to Kadiak, Cook's Inlet, and Prince William's Sound. Putting all the information together it is now my opinion, confirmed by that of Dr. Boas, that all of these examples are from Prince William's Sound. This belief is confirmed also by the fact that these are the only Eskimo throwing-sticks which show carving in relief on the back. They seem to be all made of hard spruce, and by their markings to be allied to those of the more elaborately carved specimens from Sitka in the British Museum, the United States National Museum, and elsewhere. The front or top side of the specimen has a fine ivory point for the butt end of a delicate sea otter, barbed harpoon, and a shallow groove only half its length. The finger pocket does not extend quite through to the top side.

The Salaries of Science Demonstrators.

THE enclosed fable, possibly from a missing edition of Kingsley's "Water Babies," seems to have some remote connection with the heading that has been affixed to it. O. J. L.

An aggrieved tadpole once found its way as a deputation to Mother Carey, and complained as follows, at first reading from a document, but afterwards becoming more eloquent and expressive :—

"We, your industrious and not unworthy subjects, desire to lay before you our wrongs. We cannot get out on to the land and attend meetings as the frogs do, and consequently we get no flies; yet it is we who do all the work of the pond. The frog only looks in now and then; and even if he had a mastermind (which he hasn't), his visits would have no effect. He croaks, that's what he does; he sits on the bank and eats flies, and he croaks, and so he gets listened to. As for us, we are treated no better than sticklebacks or minnows; why, there's a bloated travelling newt, who gets twice as much as we do. It's all because you old fogies are accustomed to croak yourselves. It's all—— "

"And what prospects have the minnows and sticklebacks?" here interrupted the dame. "When do they hope to leave the pond and gain advancement?"

"Why, never, of course; they've got all they'll ever get, and too much at that," grumbled the tadpole.

"And do you also intend to remain in your present condition always?"

"Not I; I intend to become a frog, and hop about, and attend meetings, and catch flies, and make a noise in the world."

"Yes; and, meanwhile, you would like these desirable appurtenances of the frog state diminished? Remember your whole pond is but a recently banked-up affair—on rather sandy soil, and the margin is narrow; it might run empty unexpectedly, you know."

"I don't care," ejaculated the tadpole; "cut off the water, and then we shall all be on dry land together; anything better than the present inequality."

"Very well," said the dame; "I know some creatures in a state of probation, not long out of the egg, who actually have to pay for the privilege of practising their future career. However, your wish that one of the recently-dug supply channels shall be stopped, so that your pond may run dry enough to let you also touch solid land as your predecessors have otherwise done, is so simple and easy to carry out, that perhaps it can be managed. Fare thee well."

A Curious Rainbow.

WHILST enjoying a general survey of the sky this evening I was giving my attention more particularly to an expanse of brilliantly white cirrus cloud, unusually complicated in its detail, when, at 7 p.m., a small inverted rainbow suddenly became apparent along the front margin of this cloud (now approaching the zenith from W.S.W.).

The bow, at first, just spanned the width of the cloud upon which it was projected, but as it increased its length a little at its "left," or south-western extremity, and as the cloud drifted slightly to "right," or north of eastwards, the bow was at last wholly projected upon a background of (apparently) clear blue sky. This last effect was extremely beautiful; the bow being so brilliantly coloured that it would, I think, hardly have escaped my notice, even if I had not first seen it upon the background of white cloud.

There was a perfect sequence of all the prismatic colours from the red, below, to the violet, above—and the curvature of the bow was remarkably rapid—and extending not more than about 2° in length.

It remained visible for about 5 or 7 minutes.

If any one can furnish me, through the medium of your columns, with an explanation of this peculiarly beautiful phenomenon, and in language that can be "understanded of the people," I shall be greatly obliged. C. O. STEVENS.

Barnet, July 12.

Effect of Lightning.

ON Tuesday, July 7, a violent storm passed over this district, and three balls of fire have been reported. Two trees were splintered, and two sheep were struck by lightning on the downs.

One sheep was not seriously injured, but the other was killed; on being struck, both sheep turned over on their backs. The one fatally injured was struck on the top of the head, the lightning passing down the animal's right jaw on to its breast; here it divided into three, and passed down both fore-legs and under the stomach. The course of the lightning on the wool was like the track of a red-hot poker. After death the aft part and belly of the sheep were greatly distended, as if with air. The blood appeared to have rushed from the head to the rear of the animal at the moment of death, for, on skinning the sheep, the neck part was found to be destitute of blood, whilst a considerable amount of blood was under the skin of the back, as if blood had escaped to that position. The sheep's mouth was distorted by being drawn aside. Close to the sheep's fore-feet a hole was made in the ground by the lightning, about the size of a quart jug. WORTHINGTON G. SMITH.

Dunstable.

A Brilliant Meteor.

I HAD the pleasure on Friday evening last, the 16th inst., of observing a brilliant meteor from a point about half-way between the towns of Blaenau and Llan Festiniog. The time was 9.10 p.m., the sky quite clear, and not dark enough for any stars to appear. The meteor appeared almost due south of my position, the length of its path being an arc of about 20°, disappearing a short distance above the horizon, and lasting about four seconds. Very little trail could be seen, as it was practically daylight. The colour appeared of a bluish tinge, and the meteor appeared to become brighter in the middle of its path.

C. H. H. WALKER.

County School, Blaenau Festiniog, July 19.

THE INTERNATIONAL CATALOGUE CONFERENCE.

THE preliminary proceedings of the Conference organised by the Royal Society to consider the preparation and publication of an International Catalogue of Scientific Literature, were reported in last week's NATURE. The Conference was brought to a conclusion on Friday, and we are now able to give the official report of the Acta in the three languages in which it is indited. From this report it will be seen that the Conference has laid a sound basis for the greatest scientific bibliography ever contemplated. The Royal Society is to be warmly congratulated upon the initiative it has taken in the matter, and the whole scientific world will be gratified at the international spirit shown in the subjoined resolutions—a spirit which prevailed throughout the Conference.

Opening Meeting, Tuesday, July 14, 1896, 11 *a.m., at the Rooms of the Royal Society, Burlington House.*

The resolutions prepared by the International Catalogue Committee of the Royal Society to serve as a basis for discussion were taken into consideration, and the following resolutions were agreed to *nemine contradicente*:—

(12) That it is desirable to compile and publish by means of some international organisation a complete catalogue of scientific literature, arranged according both to subject-matter and to authors' names.

Qu'il est désirable de compiler et de publier à l'aide d'une organisation internationale un catalogue complet de littérature scientifique classé suivant les sujets et les noms des auteurs.

Es ist wünschenswert vermittelst einer internationalen Organisation einen vollständigen Katalog der wissenschaftlichen Litteratur zusammenzustellen und zu veröffentlichen, geordnet sowohl nach dem Inhalt alsauch nach den Namen der Verfasser.

(13) That in preparing such a catalogue regard shall, in the first instance, be had to the requirements of scientific investigators, to the end that these may, by means of the catalogue, find out most easily what has been published concerning any particular subject of inquiry.

Qu'en préparant le catalogue on aura avant tout égard aux besoins des travailleurs scientifiques afin que ceux-ci puissent à l'aide de ce catalogue trouver facilement ce qui a été publié concernant les recherches sur quelque sujet que ce soit.

Bei der Vorbereitung eines solchen Katalogs soll in erster Linie Rücksicht genommen werden auf die Bedürfnisse wissenschaftlicher Forscher, so dass dieselben mit Hülfe dieses Katalogs sich leicht in der Litteratur über irgend einen besondern Gegenstand der Forschung orientiren können.

(14) That the administration of such a catalogue be entrusted to a representative body, hereinafter called the International Council, the members of which shall be chosen as hereinafter provided.

Que l'administration d'un tel catalogue soit confié à un corps représentatif, sous le nom de *Conseil International*, dont les membres seront choisis d'après les décisions prises ultérieurement.

Die Administration eines solchen Katalogs soll einer repräsentativen Körperschaft übertragen werden (die weiterhin "the International Council" genannt wird) deren Mitglieder in einer später zu bestimmenden Weise gewählt werden sollen.

(15) That the final editing and the publication of the catalogue be entrusted to an organisation, hereinafter called the Central International Bureau, under the direction of the International Council.

Que l'édition définitive et la publication du catalogue soient confiées à une organisation nommée plus tard le *Bureau Central International* sous la direction du Conseil International.

Die Herausgabe und Veröffentlichung des Katalogs soll, unter der Leitung des International Council, einer Organisation anvertraut werden, die hier "Central International Bureau" genannt wird.

(16) That any country which shall declare its willingness to undertake the task shall be entrusted with the duty of collecting, provisionally classifying, and transmitting to the central Bureau, in accordance with rules laid down by the International Council, all the entries belonging to the scientific literature of that country.

Que l'on charge chaque pays, qui se déclarera prêt à entreprendre cette tâche, de collectionner, de classer provisoirement, et de transmettre au Bureau Central selon les règles formulées par le Conseil International, tous les matériaux necessaires pour la bibliographie de la littérature scientifique de ces pays.

Jedes Land welches sich bereit erklärt, an der Arbeit theilzunehmen, soll mit der Aufgabe betraut werden, in Uebereinstimmung mit den von dem International Council vorgeschriebenen Regeln, das Material über alle einschlägigen wissenschaftlichen Veröffentlichungen des betreffenden Landes zu sammeln, provisorisch zu klassifiziren und dem centralen Bureau zu übermitteln.

(17) That in indexing according to subject-matter regard shall be had, not only to the title (of a paper or book), but also to the nature of the contents.

Que dans le classement du catalogue d'après la nature des sujets, on aura égard non seulement aux titres d'un article ou d'un livre, mais aussi à la nature de son contenu.

Bei der Aufzeichnung der Abhandlungen und Bücher soll nicht nur der Titel derselben sondern auch der Inhalt berücksichtigt werden.

(18) That the catalogue shall comprise all published original contributions to the branches of science hereinafter mentioned, whether appearing in periodicals or in the publications of Societies, or as independent pamphlets, memoirs, or books.

Que le catalogue comprendra toutes les contributions originales aux différentes branches de la science telles qu'elles sont mentionnées ci-après, paraissant soit dans les revues, ou dans les publications des sociétés, ou comme brochures indépendantes, mémoires, ou livres.

Der Katalog soll alle Original-Abhandlungen aus den weiter unten angeführten Wissenszweigen umfassen, gleichviel ob dieselben in Zeitschriften oder in Veröffentlichungen von Vereinen erschienen sind, oder in Form von Flugschriften, selbständigen Aufsätzen oder Büchern.

Second Meeting, Wednesday, July 15, 1896, 10 *a.m., at the Rooms of the Royal Society, Burlington House.*

(19) It having been proposed—

That a contribution to science for the purposes of the catalogue be considered to mean a contribution to any of the mathematical, physical or natural sciences, the limits of the several sciences to be determined hereafter—

Que devront entrer dans le catalogue toutes les contributions aux sciences mathématiques, physiques ou naturelles, les limites des différentes sciences étant déterminées ultérieurement.

In den in Rede stehenden Katalog sollen alle wissenschaftlichen Beiträge zur Mathematik und zu den Naturwissenschaften aufgenommen werden; die Abgrenzung der verschiedenen Wissenschaften ist weiterhin festzustellen.

The following amendment was moved, and, after discussion, adopted:—

That the terms of the resolution be referred to a Committee, consisting of Messrs. Armstrong, Billings, Darboux, Korteweg, Möbius, and Schwalbe, to report to the Conference at the opening meeting, on July 16.

The following resolutions were then agreed to *nemine contradicente*:—

(20) That in each country the system of collecting and preparing material for the catalogue shall be subject to the approval of the International Council.

Que la méthode employée pour réunir et préparer le matériel du catalogue dans chaque pays sera soumise à l'approbation du Conseil International.

Es soll das System, nach welchem das Material für den Katalog in jedem Lande gesammelt und vorbereitet wird, der Zustimmung des Internationalen Ausschusses unterworfen sein.

(21) That in judging whether a publication is to be considered as a contribution to science suitable for entry in the catalogue, regard shall be had to its contents, irrespective of the channel through which it is published.

Que pour juger si une publication doit être considérée comme propre a être admise dans le catalogue, on aura égard à son contenu, indépendamment du lieu et de la forme de la publication.

Bei der Beurtheilung, ob ein Beitrag zur Eintragung in de-

Katalog geeignet ist, soll der Inhalt berücksichtigt werden, ohne Rücksicht auf den Ort oder die Art der Veröffentlichung.

(22) That the Central Bureau shall issue the catalogue in the form of "slips" or "cards," the details of the cards to be hereafter determined, and the issue to take place as promptly as possible. Cards corresponding to any one or more branches of science, or to sections of such sciences, shall be supplied separately at the discretion and under the direction of the Central Bureau.

Que le Bureau Central éditera le catalogue sous la forme de fiches, le détail des fiches devant être déterminé ultérieurement, et la publication devant avoir lieu le plus promptement possible; les fiches relatives à une ou plusieurs sciences cu à l'une des sections de ces sciences seront fournies séparément au publie sous la discretion et à la direction du Bureau Central.

Das Central-Bureau soll den Katalog in der Form von "Papierstreifen" oder "Karten" ausgeben; die Details für diese Karten sollen später näher bestimmt werden; die Ausgabe soll so rasch als möglich geschehen; Karten, welche zu der einen oder andern Wissenschaft, oder zu Abtheilungen derselben gehören, sollen mit Zustimmung und auf Anordnung des Central-Ausschusses separat verabfolgt werden.

(23) That the Central Bureau shall also issue the catalogue in book form from time to time, the entries being classified according to the rules to be hereafter determined.

That the issue in the book form shall be in parts corresponding to the several branches of science, the several parts being supplied separately, at the discretion and under the direction of the Central Bureau.

Que le Bureau Central publiera, de temps en temps, le catalogue sous le forme de livre, les titres étant classés selon les règles qui seront déterminées ultérieurement.

Que la publication sous forme de livre sera divisée en parties correspondant aux diverses branches des sciences, les diverses parties pouvant être fournies séparément, sur demande.

Das Central-Bureau soll auch, von Zeit zu Zeit, den Katalog in Buchform herausgeben und sollen die Titel nach weiterhin zu bestimmenden Regeln klassifizirt werden.

Die Herausgabe in Buchform soll in Abtheilungen geschehen, welche den einzelnen Wissenschaften entsprechen, und sollen die Theile auf Verlangen einzeln verabfolgt werden.

(24) General Ferrero having moved

That the Central Bureau be located in London—

The resolution was seconded by M. Darboux, supported by Messrs. Möbius, Heller, Weiss, Simon Newcomb, Otlet, Duka, Bourcart, Dahlgren, and Korteweg, and accepted by acclamation.

Third Meeting, Thursday, July 16, 1896, *at the Rooms of the Royal Society, Burlington House.*

The appointment of Prof. Liversidge, F.R.S., as official delegate representing New South Wales, was notified.

(25) The following resolutions were agreed to *nemine contradicente*:—

That a contribution to science for the purposes of the catalogue be considered to mean a contribution to the mathematical, physical, or natural sciences, such as, for example, mathematics, astronomy, physics, chemistry, mineralogy, geology, botany, mathematical and physical geography, zoology, anatomy, physiology, general and experimental pathology, experimental psychology and anthropology, to the exclusion of what are sometimes called the applied sciences—the limits of the several sciences to be determined hereafter.

Devront entrer dans le catalogue toutes les contributions aux sciences mathématiques, physiques, et naturelles; par exemple: Mathématique, astronomie, physique, chimie, minéralogie, géologie, géographie mathématique et physique, botanique, zoologie, anatomie, pathologie générale et expérimentale, psychologie expérimentale, physiologie et anthropologie, à l'exclusion de ce qu'on nomme parfois sciences appliqués; les limites des différentes sciences seront déterminées ultérieurement.

In den in Rede stehenden Katalog sollen alle Beiträge zur Mathematik und zu den Natur-Wissenschaften aufgenommen werden, wie (z. B.) zur Mathematik, Astronomie, Physik, Chemie, Mineralogie, Geologie, zur Mathematischen und Physikalischen Geographie, zur Botanik, Zoologie, Anatomie, Physiologie, Allgemeinen und Experimental-Pathologie, Psychophysik und Anthropologie, unter Ausschluss der sog. angewandten Wissenschaften;—wobei die Abgrenzung der einzelnen Gebiete noch in der Folge festzulegen ist.

(26) That the Royal Society be requested to form a Committee to study all questions relating to the catalogue referred to it by the Conference, or remaining undecided at the close of the present sittings of the Conference, and to report thereon to the Governments concerned.

La Société Royale est priée de créer une Commission; celle-ci sera chargée d'étudier toutes les questions relatives au Catalogue, qui lui sont renvoyés par la Conférence et celles qui n'ont pas été résolues définitivement dans la Conférence, et de faire rapport sur le sujet aux gouvernements intéressés à l'entreprise.

Die Royal Society wird ersucht, ein Comité zu bilden, mit dem Auftrag, alle Fragen, welche ihr von der Conferenz vorgelegt werden und alle welche noch nicht definitiv festgelegt sind, auszuarbeiten und darüber an die beteiligten Regierungen zu berichten.

(27) Since it is probable that, if organisations be established in accordance with Resolution 16, the Guarantee Fund required for the Central Bureau can be provided by voluntary subscriptions in various countries, this Conference does not think it necessary at present to appeal to any of the Governments represented at the Conference for financial aid to the Central Bureau.

L'organisation prévue à la résolution 16 rendant probable que le fonds de garantie nécessaire au Bureau Central pourra être fourni par des souscriptions particulières dans différents pays, la Conférence estime qu'il n'est pas indispensable pour le moment de faire appel à l'aide financière des Gouvernements intéressés.

Insoferne voraussichtlich Einrichtungen im Sinne von Resolution 16 getroffen werden, erscheint es möglich, einen Garantiefonds für das Centralbureau durch freiwillige Zeichnung in den verschiedenen Ländern aufzubringen, und es glaubt daher die gegenwärtige Conferenz dass es zur Zeit nicht notwendig für das ist Centralbureau die finanzielle Unterstützung irgend einer der bei der Conferenz vertretenen Regierungen in Anspruch zu nehmen.

Fourth Meeting, Friday, July 17, 1896, *at the Rooms of the Royal Society, Burlington House.*

The following resolutions were agreed to *nemine contradicente*:—

(28) The Conference being unable to accept any of the systems of classification recently proposed, remits the study of classifications to the Committee of organisation.

Le Conférence ne pouvant accepter aucune des systèmes de classification récemment proposés renvoie l'étude des classifications au Comité d'organisation.

Die Conferenz kann keine der verschiedenen in der letzten Zeit vorgeschlagenen Classifications-Systemen annehmen und überträgt desshalb die Ausarbeitung von Classificationen dem Organisations-Comité.

The Belgian delegates expressly desired that it be placed on record that they abstained from voting on this resolution.

(29) That English be the language of the two catalogues, authors' names and titles being given only in the original languages except when these belong to a category to be determined by the International Council.

L'anglais sera la langue des deux catalogues. Toutefois les noms d'auteurs et les titres des mémoires seront donnés seulement dans la langue originale à moins que cette langue n'appartienne à une catégorie qui sera déterminée par le Conseil International.

Es soll Englisch die Sprache der beiden Cataloge sein. Die Namen der Verfasser und die Titel sollen indessen ausschliesslich in der Original-Sprache veröffentlicht werden, ausgenommen in den von dem Internationalen Ausschuss zu bestimmenden Fällen.

(30) That it be left to the Committee (of the Royal Society) to suggest such details as will render the catalogue of the greatest possible use to those unfamiliar with English.

Le Comité aura à proposer tous les détails qui seraient de nature a rendre plus facile l'usage du catalogue dans les pays de langues étrangères à la langue anglaise.

Es wird dem Comité der Royal Society überlassen, alle Anordnungen zu treffen welche den Gebrauch des Cataloges für die nichtenglischen Sprachen zu erleichtern geeignet sind.

(31) That it is desirable that the Royal Society should be informed, at a date not later than January 1, 1898, what steps (if any) are being taken, or are likely to be taken, in the countries whose Governments are represented at the Conference, towards establishing organisations for the purpose of securing the end had in view in Resolution 16.

Qu'il est désirable que la Société Royale reçoive communication, au plus tard le 1[er] janvier, 1898, des démarches qui ont été prises ou seront prises par les gouvernements des pays représentés à la Conférence pour l'exécution de la résolution 16.

Es ist wünschenswerth, dass die Royal Society nicht später als bis zum 1. Januar 1898, darüber verständigt werde, welche Schritte von Seiten der Länder welche Delegirte zur Versammlung gesendet haben gethan oder in Aussicht genommen sind, um Einrichtungen zu treffen welche die Durchführung des Beschlusses 16 ermöglichen.

(32) That the Delegates, in reporting to their respective Governments the Proceedings of the Conference, should call immediate attention to Resolutions 16 and 31.

Que les délégués sont invités en faisant rapport à leurs gouvernements à attirer spécialement l'attention sur les résolutions 16 et 31.

Die Dèlegirten wollen in den Berichten an ihren Regierungen über den Verlauf der Versammlung, die besondere Aufmerksamkeit auf die Beschlüsse 16 und 31 lenken.

(33) That January 1, 1900, be fixed as the date of the beginning of the catalogue.

Que le début du catalogue soit fixé au 1[er] janvier, 1900.

Es soll der 1. Januar 1900 als Datum für den Anfang des Cataloges festgesetzt werden.

(34) That the Royal Society be requested to undertake the editing, publication, and distribution of a verbatim report of the Proceedings of the Conference.

La Société Royale est prié de se charger de la confection, de la publication, et de la distribution d'un compte rendu textuel des travaux de la Conférence.

Die Royal Society wird ersucht, die Abfassung, Veröffentlichung und Versendung eines wörtlichen Berichtes der Verhandlungen der Conferenz zu übernehmen.

(35) That the *procès verbal* of the Conference be signed by the President and Secretaries.

(36) That this Conference requests the Royal Society to express to the Lord Mayor of London and to Dr. L. Mond their grateful, hearty appreciation of the hospitality shown by them to the Delegates.

(37) On the motion of M. Darboux, a vote of thanks to Sir John Gorst, for presiding over the Conference and his conduct in the chair, was passed by acclamation.

(38) On the motion of Prof. Weiss, a vote of thanks to the Royal Society, for their cordial reception of the Delegates, was unanimously carried.

Signed { JOHN E. GORST, President.
HENRY E. ARMSTRONG }
WALTHER DYCK } Secretaries.
F. A. FOREL }

ARCHÆOLOGICAL STUDIES IN MEXICO.

MR. WILLIAM H. HOLMES, who has been so long and favourably known in connection with the Smithsonian Institute at Washington, has lately been placed in charge of the Department of Anthropology at the Field Columbian Museum at Chicago, and has now issued from his department the first volume of what promises to be a most interesting series of anthropological publications.

Soon after Mr. Holmes had moved to his new post, Mr. Alison Armour, of Chicago, who takes a keen interest in archæological studies, invited (to quote from Mr. Holmes's preface) a number of "gentlemen representing different branches of scientific research to accompany him in his steam yacht *Ituna* on a voyage to Mexico. Three months were spent in that most interesting country, mainly in the States of Yucatan, Chiapas, and Oaxaca. The writer (Mr. Holmes) was a member of the party, and, as Curator of Anthropology in the Field Columbian Museum, was expected to examine and describe such archæologic remains as happened to be encountered during the journey."

Mr. Holmes made excellent use of his opportunities, and we now have the first instalment of his Report, intituled "Archæological Studies among the Ancient Cities of Mexico," dealing particularly with the monuments of Yucatan.

After an introductory chapter (with excellent illustrations), which treats of the materials and methods used in construction of Maya buildings, Mr. Holmes describes in turn the different groups of ruins which were visited, beginning with those on the islands lying close to the eastern coast of the peninsula, Mugeres, Cancun, and Cozumel. An excellent reproduction of a photograph, taken by Mr. E. H. Thompson, shows the very curious portal of a small temple on the last-named island, with one of the two supporting columns formed of a kneeling human figure.

On first opening Mr. Holmes's report I turned over the pages hastily to find an account of the ruins of Tuloom, but was doomed to disappointment. On page 75 is the following paragraph: "The most important group of ruins on the east coast of Yucatan, so far as the remains have been reported, is that known as Tuloom. It is situated on a high bluff overlooking the sea, some twenty-five miles south-west of San Miguel, the main settlement of the island of Cozumel. It was visited by Stephens in 1840, and he has given us the only available account[1] published up to date. This place must have been an important stronghold of the ancient Mayas, although it was not visited by the early Spaniards, so far as our records show. It is a remarkable circumstance that this place is held to-day by a Maya tribe which has never been permanently subdued by the Spaniards or Mexicans, and which now holds it as an outpost, being at war with the Mexican Government and with all intruders, whatsoever their nationality. At the time of our visit to Cozumel there were special symptoms of hostility, and the sub-chief, to whom the Tuloom district was entrusted by the principal chief, whose headquarters are some distance inland, had recently been summarily executed for permitting trade between his people and the inhabitants of Cozumel. It was natural, therefore, when the leading citizen of Cozumel, Don Pedro Perez, assured us that we would certainly be fired upon by the hostiles if we attempted to land, that the project of studying this ruin was abandoned."

I most fully sympathise with the travellers in their disappointment in failing to examine this important site, which, as far as I know, has never since the time of Stephens and Catherwood been visited by any one capable of giving an adequate description of the ruins.

The yacht then sailed round the north of the peninsula, and the travellers were landed at Progreso, whence a land journey was taken to visit the celebrated ruins of Uxmal, Izamal, and Chichén Itzá.

Uxmal is so easy of access, and has been so often visited, photographed, and described, that Mr. Holmes could not be expected during a short visit to discover anything which would add to our previous knowledge; but the admirably clear description which he gives of the ruins is accompanied by a plan and by a most carefully compiled panoramic view of the site, which will prove of the greatest assistance to the reader.

Plate vii. gives a photograph of an inscribed column or stela discovered by Mr. Thompson, which is of the utmost value, as so very few examples of carved hieroglyphic inscriptions have as yet been found in Yucatan, and a comparison of the Yucatec inscriptions with the numerous inscriptions found in Guatemala and Chiapas

[1] Stephens' "Incidents of Travel in Yucatan," vol. i. p. 390.

is a matter of the highest interest to students of American archæology.

I trust that in a future publication Mr. Holmes will give us a drawing of the whole of the inscription on this stela, as only a portion of it is shown in the photograph.

After a glance at Izamal the travellers went on to Chichén Itzá, where they remained for a week. As I was myself encamped for five months at Chichén Itzá in 1889, engaged in clearing and examining the ruins, I am well able to appreciate the great extent and excellence of the work accomplished by Mr. Holmes during the short time at his disposal. The property on which the ruins stand has recently passed into the possession of Mr. E. H. Thompson, formerly United States Consul in Merida, who has for many years been an ardent student of Maya archæology, and amongst other work has made an exhaustive examination of the ruins of Labná for the Peabody Institute at Harvard. Now that Mr. Thompson is resident at Chichén, we may look forward to many interesting discoveries by one who has had such long experience in the field.

I can only express my regret that at the time of his visit Mr. Holmes had not yet received copies of my plans and photographs (the first portion of which has been published in the *Biologia Centrali Americana*, vol iii.), as his corrections and criticisms made on the spot would have been of the utmost value.

Mr. Holmes's work has been so well done, and must be so acceptable to all students of the subject, that I have some fear that it may seem almost ungracious on my part to note what appear to me some few errors which my longer residence in the ruins enable me to detect.

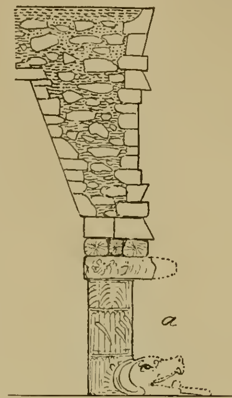
On p. 114, the mutilated figures in the niches on either side of the mask over the doorway of the "Iglesia" are not human figures, but apparently humanised animals, one being a turtle and another an alligator.

On pp. 116–117, the curious round tower known as the "Caracol," is figured and described as symmetrically placed on its double terraces; but I found the upper terrace to be curiously uneven, and unsymmetrically placed on the lower one.

On p. 119, Mr. Holmes states: "The exterior conformation of this strange tower can be made out in part only. The lower wall is of ordinary masonry, finished in plaster, and broken only by the four entrances. It rises nine or ten feet to the base of the formidable, five-membered moulding, which projects two feet from the wall face and is five feet in width, being the only example of its kind in Yucatan. The upper margin is opposite the middle of the arch slope within, as seen in the section. The masonry at this level is four feet thick.

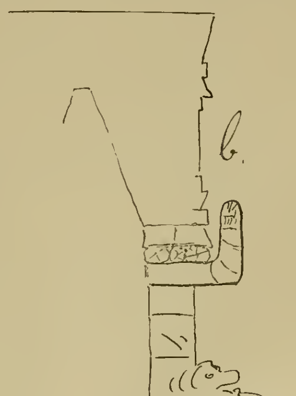
"In studying this part of the building the very interesting question arose as to whether the exterior wall surface above this moulding rose vertically or whether it sloped inwards toward the upper turret. I had the good fortune to find one vertical stone, representing the first course above the moulding, in place, and this I regard as conclusive proof that the upper wall-zone was vertical. This conclusion is confirmed by the fact that in all cases in Yucatan and Chiapas, so far as I have observed, where the upper mural zone slopes, it includes with it in the slope not only all the courses above the medial mouldings, but the medial mouldings themselves, whereas in this case the mouldings are vertical." This conclusion is of considerable importance, and shows that I have fallen into an error in my figuring of the upper part of the Caracol (*Biol. Centr. Am.*, vol. iii. plate 20), and makes me regret all the more that my plans and photographs were not in Mr. Holmes's hands when he was at Chichén.

On p. 124, in describing the "Castillo," Mr. Holmes suggests that the balustrades of all four stairways ended in serpents' heads; but this is the case in the northern stairway only. I moved many tons of earth and stones in order to uncover the base of the western stairway, and found the end of the balustrade to be without any ornament whatever. I cannot agree with Mr. Holmes in the assumption that the corners of the pyramidal foundation were ornamented with great serpents' bodies "following in and out the nine-terraced steps."[1] The structure of the



rounded corners of the pyramid can be fairly well made out at the north-east angle; but in all probability it was thickly overgrown, and so escaped notice.

In describing the portal of the Castillo, and the portal of the temple on the wall of the Ball Court (the temple of the Tigres), Mr. Holmes has just failed to catch the full structure of the serpent columns. These

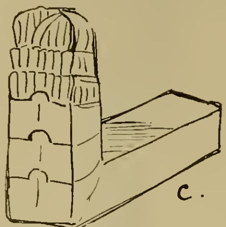


columns are markedly characteristic of Chichén Itzá, and the portals of no less than six of the temples were supported by them. One is figured in the frontispiece (Plate 1), and again in the sections of the Castillo and of the Ball Court temple. The figure here reproduced (*a*) is from the section of the Castillo (p. 123). The more correct drawing would be as in (*b*), the projection from

the capital (c) of the column, turning upwards and being carved to represent the rattles on a rattlesnake's tail, with the addition, in some instances, of a plume of feathers.

It is this peculiar form of capital which has done so much to ensure the ruin of the façades of the Chichén Itzá temples; for the weight of the projecting tail tilted the capital outwards as the wooden beam above it decayed.

Some of these queer-shaped capitals (c) can be found lying on the slopes or at the bottom of the pyramidal



C.

foundations of the temples; and it is only in the case of the Castillo, where the projecting tail has been broken off, as shown in Fig. a, that the façade of the temple has escaped destruction.

On page 132 it is stated that "the lintel beams of the doorway (temple of the Tigres), three in number, and set as indicated in the section, are covered with well-executed glyphs." For "glyphs" must be here read "ornaments," as there is no trace of any hieroglyphic inscription.

I notice that in describing the painted mural decoration of the interior of this temple no notice is taken of the picture above the doorway of a human sacrifice, and I greatly fear it must have disappeared since I traced it in its already mutilated condition in 1889.

Mr. Holmes was not able to attempt any detailed examination of the great group of colonnades and temples which lie to the east and south-east of the Castillo. These I surveyed in 1889, but had no time to make satisfactory excavations, and I greatly envy Mr. E. Thompson the opportunity he has of making a thorough exploration of these most interesting remains.

There is one point on which I hope Mr. Holmes will give us some further enlightenment. On page 102 he states, without quoting his authorities, that Chichén Itzá was occupied by its builders for nearly 200 years after its discovery by the Spaniards.

I have endeavoured to show in my own account of the ruins (*Biol. Centr. Am.*, vol. iii. pp. 5–9), that the statement that the Spaniards encamped at Chichén in 1528 must be received with caution, and neither Bishop Landa, nor the report drawn up at Valladolid in 1579, appear to me to indicate any occupation of Chichén by the Mayas at the time of the conquest, although it may still have been held in reverence as a place of pilgrimage.

Part i. of Mr. Holmes's report ends with the description of Chichén Itzá. The descriptions throughout are lucid, and the illustrations numerous and excellent. All students of American archæology will eagerly look forward to the succeeding issues, and will, I feel sure, join me in hearty congratulations to Mr. Holmes on the excellence of his work, and to the Field Columbian Museum on having thus been able to utilise his services; and all of us, who have expensive scientific hobbies, must wish that there were more Alison Armours in the world to give such splendid and timely help to scientific research.

ALFRED P. MAUDSLAY.

MEASUREMENT OF CLOUD HEIGHTS AND VELOCITIES.[1]

THE study of the form and motion of the clouds has been a favourite subject with meteorologists and physicists from the earliest times. Among the first works, since the invention of printing, may be mentioned one by J. Alkindus (Venice, 1507), dealing with clouds in general, and one on the height of clouds, by J. Bernoulli, "Nova ratio metiendi altitudines nubium" (Lipsiae, 1688). But it is only during the last quarter of a century, since it has been recognised that cyclones and anticyclones form part of the general circulation ot the atmosphere, that the importance of a systematic study of the upper air-currents by means of clouds has been fully appreciated. For this purpose various methods, both with and without instruments, have been employed. In 1878 the Meteorological Council decided upon undertaking a series of experiments at the Kew Observatory, with a view of obtaining records of the height and velocity of clouds, by means of photography, for which purpose cameras fitted with theodolite mountings, and provided with altitude and azimuth circles, were used. The results of subsequent investigations, in which the exposure of the plates was effected by electrical means, were published in the *Proceedings* of the Royal Society, vol. xlix. p. 467. In vol. viii. p. 108, of the *American Meteorological Journal*, Mr. Rotch gives an account of the measurements of cloud velocities at Blue Hill Observatory, Massachusetts, by timing the movement of shadows cast by the clouds at points whose distance apart was known. During the present year, owing to the action taken by the International Meteorological Committee, cloud observations are being made in all parts of the globe, and instructions for the use of special instruments have been drawn up, at the request of the Committee, by Dr. Hildebrandsson, of Upsala. The majority of stations, if they use instruments at all, restrict themselves to the use of simple nephoscopes, which give the direction and apparent velocity of the clouds, by means of a mirror and graduated circles; in these instruments the observations are not influenced by the effects of perspective, which are the same in the sky and in the mirror. At

some of the principal observatories theodolites and photogrammeters are being used. Each of the last two methods has its advantages and disadvantages; theodolites are simpler and cheaper, while photogrammeters require a certain amount of skill in photography. The

[1] "Wolkenhöhenmessungen," von E. Kayser (*Schriften der Naturforschenden Gesellschaft in Danzig*, 1895); "Des principales méthodes employées pour observer et mesurer les nuages," par H. H. Hildebrandsson et K. L. Hagström (Upsala, 1893).

theodolite requires the two observers—each placed at one end of the measured base—to agree by telephonic correspondence on one fixed point in the cloud, which it is not always easy to do, as well as on the precise instant at which the observation should be taken; the calculation of the observations is subsequently made from trigonometrical formulæ, or by a slide-rule, or plotting machine. The photogrammeter, which is a theodolite provided with a small telescope and a camera obscura, possesses one great advantage from the fact that the two observers have no need to agree as to the special point to be observed: it is sufficient that both photograph the same part of the sky at the same moment. On each photographic plate the coordinates of a point of intersection are known, and by placing it upon a glass scale graduated to millimetres the coordinates of as many points as may be desired can be fixed; it is only necessary to determine, once for all, how many minutes correspond to a millimetre on the plate. Once the coordinates are found, the calculations can be made as in the case of the theodolites. As these researches require the calculation of a great number of observations, it is indispensable that the methods employed in reducing them should be as simple as possible. This desideratum has been solved by M. Akerblom, in a very satisfactory manner, in a pamphlet entitled "De l'emploi des Photogrammeters"

(Upsala, 1894), which has been distributed by Dr. Hildebrandsson to intending observers. Easy methods of reduction, giving approximately correct results, have also been devised by General R. Strachey and Sir G. Stokes.

We have before us a valuable investigation by Dr. Kayser, containing some 1500 cloud measurements made under the auspices of the Philosophical Society of Danzig, between May and August 1895, by means of photogrammeters. In various respects the camera used appears to be an improvement on some of the instruments hitherto adopted, being of simple construction, well balanced, and combining ease of movement with necessary rigidity, while the altitude and azimuth circles are sufficiently large to admit of accurate reading. The accompanying plates are reproductions of a pair of photographs of a cumulus cloud observed by this means on May 25, 1895. The mean height of the cloud from several measurements was found to be 1714 metres, the distance between the two observing stations being about 679 metres. In order not to delay the publication of the Society's volume, no classification of the heights of the various clouds has been made; but in the *Meteorologische Zeitschrift* for May, Dr. Sprung has attempted this, and finds the mean values in metres to be as follows:—Stratus, 1704; cumulus, 2856; strato-cumulus, 2196; alto-cumulus, 4098; cirro-cumulus, 6834; cirrus, 10,043. The daily variation of altitude cannot be deduced from these observations, because they were not distributed sufficiently uniformly throughout the day. Dr. Kayser's work contains useful materials for the study of observers during the international cloud year, and we are glad to see that the observations are to be continued this summer.

NOTES.

On Wednesday in last week, the Queen invested Lord Kelvin with the Riband and Badge of a Knight Grand Cross of the new Royal Victorian Order.

Sir William MacCormac has been elected President of the Royal College of Surgeons of England.

General M. Rykatchef has been appointed Director of the Central Physical Observatory, St. Petersburg, in the place of Dr. H. Wild, resigned. For many years General Rykatchef has had charge of the maritime meteorological branch of that Observatory.

In the House of Commons on Friday last, Sir S. Northcote asked the President of the Board of Trade if he would introduce this Session a Bill to deal with the metric system, in order that chambers of commerce and other parties interested might have sufficient time during the recess to consider the proposals of Her Majesty's Government on this subject. Mr. Ritchie replied that he would be glad to introduce the Bill, but without any intention of proceeding with it this Session.

The large male Indian elephant which was brought home by the Prince of Wales from India in May 1876, and which died in the Zoological Society's Gardens on March 8 last, has been successfully mounted by Mr. E. Gerrard, jun. The specimen is at present placed in the Central Hall of the Natural History Museum, just opposite the principal entrance; but it will be ultimately moved to the Mammal Gallery, which is now in process of rearrangement, when space has been found for it.

A fine example of the Pangolin, or Scaly Anteater, is now on view at the Zoological Society's Gardens, having been placed there, on deposit, by the Hon. Walter Rothschild. Pangolins are seldom seen in captivity, being very difficult to keep in good health. There has been no example of this form in the Society's collection for nearly twenty years. The present specimen, which seems likely to do well, belongs to the species called the Short-tailed Pangolin (*Manis temmincki*), of which a good figure is given in the third volume of "The Royal Natural History," lately published. It is said to have been obtained in the Transvaal.

Dr. Klein recently delivered three lectures on the subject of "Recent Researches in the Identification of the Typhoid Bacillus and the Cholera Vibrio," being the Harben Lectures in connection with the British Institute of Public Health. The lectures are the property of that Institute, and will be published in its official organ, *The Journal of State Medicine*. The first lecture has just been published in the July number. The other lectures will appear in the August number.

By means of a rearrangement of existing scholarships at the Charing Cross Hospital Medical School, and by the establishment of a special fund, memorials have been founded to Dr. Livingstone and Prof. Huxley, both old students of the school. The memorial to Livingstone takes the form of an entrance scholarship of 100 guineas per annum, and that to Huxley of (1) an entrance scholarship of £55, open to the sons of medical men; (2) a second year's prize in anatomy and physiology; and (3) a lectureship dealing with recent advances

in science and their bearing on medicine and surgery. The first of these Huxley lectures will be delivered in the anatomical theatre of the Medical School on Monday, October 5, by Dr. Michael Foster.

THE Bertillon system of anthropological measurements has just been adopted at the Sing Sing States Prison.

THE 126th meeting of the Yorkshire Naturalists' Union will be held at Staithes, for the investigation of the neighbouring coast, and the Easington and Roxby Woods, on Bank Holiday Monday, August 3, 1896.

THE annual meeting of the Society of Chemical Industry was held as we went to press last week. In the course of his presidential address, Mr. Thomas Tyrer compared the German and English chemical industries, and remarked: "The real cause of the progress and prosperity of the former is to be found in the superior qualifications of the directing minds. Germany does not owe her progress alone to protective tariffs, nor to the superior discipline of her workmen, but to her thorough system of education, elementary and secondary. Dr. Seth Low's definition of a college as a place for liberal culture and a university as a place for specialisation based on liberal culture, is true of Germany, and should be so for Britain. The agitation for a teaching university for London is, therefore, a good thing. Moreover, no scheme of education will approach perfection unless it provides for the graduated affiliation of schools and colleges with universities. The City Companies and Guilds of London are taking a prominent part in supplying the great need for scientific training; and with all the resources of this wealthy country, the practicality of its people, and the public spirit of its citizens, we ought to remain very little longer in a state of educational backwardness. It is but necessary that the State shall define the need, and the steps by which that need shall be met, and then resolutely carry them out." The Council recently instituted medals to be awarded at intervals of not less than two years for conspicuous services rendered to applied chemistry by research, discovery, invention, or improvement in processes. The first award was made, at last week's meeting, to Mr. John Glover, inventor of the "Glover" tower, the introduction of which marks an important development in alkali manufacture. The newly-elected President of the Society is Dr. Edward Schunck, F.R.S.

THE naturalists of the Marine Biological Association have recently been paying particular attention to the question of the collection of fishery statistics, and an important report on the subject has just been received by the Council of the Association. In this report an account is first given of the statistics at present collected and published by the Board of Trade relating to sea-fisheries in England. It is pointed out that the methods at present adopted for collecting the statistics are not such as to give confidence in the accuracy of the returns, whilst their inadequacy in plan and extent cannot be questioned. The defects upon which emphasis is principally laid are the want of sufficient discrimination between the species of fish landed, the lack of all information as to the locality of capture of the fish, and the fact that no attempt is made to distinguish between the products of different methods of fishing. Various suggestions are made as to the methods by which the statistics could be improved, and it is maintained that the only really satisfactory course would be to require the master of each fishing vessel to supply the Board of Trade with correct returns of the fish caught, and of the locality of their capture. In the case of the larger vessels, at any rate, such records already exist, and are supplied by the master to his owners. All that is required is that copies of these records should be furnished to the proper officers, so that the information may be utilised for the general benefit of the public and of the fishing industry. The report will be published, in full, in the forthcoming number of the *Journal* of the Association.

As previously announced, the autumn meeting of the Iron and Steel Institute will be held at Bilbao on September 1-4. The Local Reception Committee, which comprises all the various local authorities, corporations, ironmasters and miners, with Don Julio de Lazurtegui as honorary secretary, has now drawn up an outline programme of the meeting. The Orient Company's s.s. *Ormuz*, which has been detailed to convey the members to Spain, and to serve as a "floating hotel," will leave Tilbury for Portugalete at noon on Saturday, August 29. On the arrival of the *Ormuz* at Portugalete, the Reception Committee will go out to meet the steamer, and will welcome the visitors. Immediately after this visit the members will visit the new harbour and breakwater now in course of construction, and continue up the river Nervion to Bilbao, inspecting on their way the electric installation of MM. Coiseau Couvreux et Félix Allard, for making the mammoth concrete blocks used in the construction of the breakwater. On Tuesday, September 1, the members will formally visit Bilbao, where they will be welcomed by the Alcalde in the *Salon de Actos* of the Provincial College. The general meeting for the reading and discussion of papers will then be held. In the afternoon the members will visit the steel works of the Sociedad de Altos Hornos; and in the evening, there will be a reception by the Alcalde in the new Municipal Buildings. On Wednesday, September 2, after the general meeting and luncheon, the members will visit the steel works and coke ovens of the Sociedad La Vizcaya, and afterwards the tin-plate works of the Sociedad La Yberia. In the evening, there will be a grand tennis match (the basque ball game of *Pelota*) in the Euskalduna Tennis Court, and also a *fête champêtre* and concert, at which the Bilbao Orpheon of 100 members have consented to sing, in the Campos Eliseos. There will be no general meeting on Thursday, September 3, the whole of the morning being devoted to visiting the mines. The *Ormuz* will leave Portugalete on the following day for Santander, where the mines will be visited. Short stays will be made at San Sebastian and St. Jean de Lux on the way back to London, which will be reached on Saturday, September 12.

THE sixty-fourth annual meeting of the British Medical Association will be held at Carlisle, on July 28-31. The President-elect is Dr. Henry Barnes. An address in medicine will be delivered by Sir Dyce Duckworth, and one in surgery by Dr. R. Maclaren. The scientific business of the meeting will be conducted in nine Sections. The President of Section A (Medicine) is Dr. George F. Duffey; and among the subjects down for discussion are: the treatment of cardiac failure, with special reference to the methods of passive exercise, active exercise and baths; anæmia, its varieties, causation, associated pathology, and treatment; tuberculosis, its prevention and cure. In Section B (Surgery), presided over by Dr. A. Ogston, Dr. Macintyre will demonstrate the use of Röntgen rays in surgery, with special reference to the cavities of the body, instantaneous photographs, and fluorescent screens. Section C is devoted to obstetrics and gynæcology; the President is Dr. J. H. Croom. Sir Joseph Ewart, President of Section D (Public Medicine), will open the Section with an address. Among the subjects to be brought forward are: Medical research in relation to hygiene, vaccination and revaccination with animal vaccine in Germany, and diphtheria in town and country. Section E (Psychology) will be opened by the President, Dr. J. A. Campbell, with an address. Most of the papers down for reading and discussion in this Section belong to pathological psychology. An introductory address will be delivered to Section F (Pathology and Bacteriology) by the President, Dr.

Sheridan Delépine; and there will be a discussion on the relation of the morbid conditions dependent on (or associated with) the presence of streptococci. Dr. David Little will preside over Section G (Ophthalmology), Dr. J. Finlayson over Section H (Diseases of Children), and Dr. T. F. I'Anson over Section I (Medical Ethics). A number of garden parties and other social functions have been arranged, and these will help to lighten the large amount of work which the various Sections will have to do.

IT was shown by M. H. Moissan, about three years ago, that when iron was saturated at 3000° C. with carbon, and then cooled under a high pressure, a portion of the carbon separated out in the form of diamond. It occurred to M. Rossel (*Comptes rendus*, July 13), that the conditions under which very hard steels are now made, should also result in the formation of diamonds; and an examination of a large number of samples of such steel has shown that this is really the case. The diamonds are obtained by dissolving the metal in acid, and then subjecting the residue to the action of concentrated nitric acid, fused potassium chlorate, hydrofluoric and sulphuric acids successively. The crystals are very minute (about 15 $\mu\mu$), the largest attaining only 0·5 mm. in diameter, but they present all the chemical and physical properties of true diamonds.

THE detection and estimation of small amounts of marsh gas in air is a problem of considerable practical importance in the ventilation of mines, and numerous instruments having this object have been designed. In the May number of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Mr. E. Hardy describes a new apparatus for this purpose which presents many novel features. The principle utilised is the variation of the velocity of sound in a gas with its density. The air under examination is forced through a small organ pipe, and the note thus produced compared with that given out by a second pipe fed under parallel conditions with pure air, the number of beats per second produced giving a measure of the methane present, the apparatus being so arranged that the moisture, carbonic acid, and possible variations of temperature exert no influence on the result. Three types of instrument are constructed, portable, fixed, and self-recording. In the second type a telephone from any convenient place is put in connection with two microphones placed on the organ pipes, so that by simply counting the number of beats, the manager can instantly recognise from his office the presence of fire-damp in the part of the mine from which the air is being drawn, 1 per cent. of methane giving about three beats per second. The only drawback to this ingenious apparatus is that it is rather complicated in detail, and therefore costly, especially in the self-recording type; but the advantages of extreme simplicity in actual use, combined with the convenience attaching to the telephone, will doubtless outweigh this in practice.

IN a paper on gall-making coccids, contributed by Mr. C. Fuller to the *Agricultural Gazette* of New South Wales (vii. 4), some details are given concerning the genus Brachyscelis, the members of which live exclusively upon species of Eucalyptus, causing the growth of woody galls, in the heart of which they dwell. These coccids are popularly known in Australia as "gall-makers," but the gall-growth differs from the "meal" of the mealy-bug and the "scale" of the bark-louse—which are other Australian species of Coccidæ—in that it is brought into existence at the actual and direct expense of the tissue of the plants, whilst the meal and the scales are products secreted or excreted from the bodies of the insects themselves. The larvæ of all Brachysceles are so similar in appearance as to afford no sufficient characteristics for the determination of species. The male galls take the form of short cylindrical tubes, not exceeding six lines in length, and generally growing upon the leaves. The female galls exhibit a great variety of forms, which supply the easiest means of distinguishing the different species, and which vary in length from half an inch to six or seven inches. Some resemble cones, others nuts and fruits, whilst the latera growths, due to *B. duplex*, are not unlike leaves. Occasionally supported on stalks, they are more often sessile upon the branches, twigs, or leaves from which they spring. These abnormal members of an aberrant group like the Coccidæ should repay further study.

Do varieties of peas run out? This problem is dealt with in *Bulletin* No. 131 of the Michigan Agricultural Experiment Station, and the answer is that varieties at least lose their original characteristics. Such "running out," however, does not necessarily imply deterioration, as sometimes it is merely a changing of characters. Accurate descriptions accompanied by drawings are kept of varieties of peas grown at the station. These serve to show that varieties change from year to year—even the old standard sorts, the characters of which are supposed to be firmly fixed. The foliage and habit of the plants are found to be less variable than the peas themselves, which are generally the object of selection. The variety Stratagem was grown from seed obtained from three different dealers. In all, the characteristic dark green foliage, stalky, angular veins, and exceedingly short nodes of the variety named were apparent. But the pods, though irregular and varying in each sample, yet, taken as a whole, were distinctly different. In two of the samples the pods were fairly uniform, but in the third they were so irregular—probably reversions to one of the parents—that the peas were almost worthless. It is a matter of common observation that seed peas of the same variety, especially the wrinkled sorts, differ in colour as supplied by different seedsmen. In several cases peas grown on the station grounds have changed the colour of their seed within the last four years.

A BRIEF statement of the facts as to the anti-cholera serum experiments carried out by Prof. Kitasato, of Tōkyō, is made by Dr. A. Nakagawa in the current number of the *British Medical Journal*. Preliminary experiments in the laboratory for ascertaining the curative action of the serum were carried on in this wise: A number of guinea-pigs were inoculated with several times the fatal dose of the virus, so that the untreated animals died within twenty hours after such inoculation. At the expiration of each successive hour injections were made in some of the animals, and it was shown that those treated not later than seven hours after the inoculation of the virus were cured, while those in which the injections were made after the lapse of seven hours could not be saved by the serum. In other words, if injected during the first third of the entire course of the disease (thus experimentally produced) the serum can be considered curative. Cases of cholera were afterwards treated with anti-cholera serum at the Hiroo Hospital, Tōkyō. Of 270 cases admitted, 138 died, which gives a rate of mortality of 51·1 per cent. Anti-cholera serum was employed in 193 cases only, owing to the fact that the supply of serum was inadequate to allow it to be used in all cases. The rate of mortality among Japanese in nearly all the previous epidemics, as well as that of the last epidemic, has always been about 70 per cent. Without claiming to draw, from a number relatively so small, the final conclusion that the serum treatment was attended with the reduction of 20 per cent. in the mortality statistics, it is evident at least that the result of the new therapy was not an unfavourable one. Moreover, Dr. Nakagawa thinks there is reason to believe that, with a sufficient supply of very efficient serum, the rate of mortality can still be lowered.

STUDENTS of Japanese culture will be interested in a paper on "Anatomy and Æsthetics among the Japanese," in *Globus*

(Band lxx. p. 21), by Max Buchner, and in the folk-lore contained in P. Ehmann's paper on "Popular Notions in Japan," in the current volume of *Œsterreich. Monatsschr. für den Orient*, p. 58.

DR. F. SOSSET has published in the *Revue de l'Université de Bruxelles* (vol. i. p. 481) a painstaking account of weaving in Ancient Greece, and has employed various representations from Greek vases and other sources to illustrate the accounts given by the classical writers. Those who are interested in the development of the industrial arts should consult his memoir.

THE contemporaneity of Man with the Gigantic Fossil Sloth Megalonyx appears to be now established, Mr. H. C. Mercer having recently obtained distinct evidence on this point in the Big Bone Cave, Van Buren County, Tennessee. The full report, which will be published by the Archæological Department of the University of Pennsylvania, will be awaited with interest, as it should provide data towards the solution of the problem of the length of time man has existed in the New World.

THE British Museum possesses several very beautiful and valuable examples of Ancient Mexican mosaic work. These, together with examples in other European museums, have been figured and described by Mr. A. Oppel in *Globus* (Band lxx. p. 4). The most important material of these mosaics is turquoise; in none is it wanting, and on one shield in Vienna it is the only stone employed, tesseræ of shell (white, light red, and purple-red), nacre, malachite, gold, obsidian, and other materials are also employed. The masks, head-dresses, shields, and other objects which were decorated in this sumptuous manner, were evidently employed in the ancient religious ceremonies.

UNDER the title of "Common Sense in Chess," an abstract of twelve lectures delivered by Mr. Lasker in London last year, has been published by Messrs. Bellairs and Co. As an exposition of the methods of this brilliant player, this pamphlet will be read with much interest, more especially since, instead of the exhaustive variations of the openings customary in works of this class, an attempt is made to base the conduct of the game upon a few simple general principles. These principles are advanced in the opening chapter as empirical rules, to which the games worked out in the subsequent chapters supply the proof.

WE are glad to be able to report a considerable step in advance made by the Observatory at Athens by the publication, from the 4th ult., of a daily weather report containing twenty-five stations in Greece, and about double that number of exterior stations. The report is accompanied by two charts, one showing the isobars and general meteorological conditions at 8 a.m. over a large part of Europe, and one showing wind and temperature over Greece and adjacent islands. Observations have been made regularly at the Athens Observatory since 1858, some of which have been published and discussed: but we are not aware that the issue of synchronous charts, in the form adopted by other countries, has been before attempted.

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mrs. Turner-Turner; a Huanaco (*Lama huanacos*, ♂) from Bolivia, presented by Mr. J. F. Schwann; a Passerine Owl (*Glaucidium passerinum*), European, presented by Miss Bloxam; four Rough-keeled Snakes (*Dasypeltis scabra*), a Lineated Boodon (*Boodon lineatus*), a Rhomb-marked Snake (*Psammophylax rhombeatus*), a Delaland's Lizard (*Nucras delalandii*) from South Africa, presented by Mr. Frederick A. Story; an Agile Wallaby (*Halmaturus agilis*, ♀) from Australia, an Indian Python (*Python molurus*) from India, seven Peruvian Snakes (*Tachymenis peruviana*), nine —— Lizards (*Liolæmus* sp. inc.), five Gay's Frogs (*Calyptocephalus gayi*), six Bibron's Frogs (*Paludicola bibroni*) from Chili, deposited; a Brazza's Monkey (*Cercopithecus brazzæ*, ♀) from French Congoland, a Tayra (*Galictis barbara*) from South America, a Patagonian Conure (*Conurus patagonus*) from La Plata, purchased.

IN our report of the celebration of the Kelvin jubilee, on p. 177 of our issue of June 25, Prof. Cleveland Abbe was inadvertently credited with being the "head of the Meteorological Office, Washington." To prevent misapprehension, it may be desirable to state that the responsible position of Chief of the U.S. Weather Bureau is actually filled by Prof. Willis L. Moore.

OUR ASTRONOMICAL COLUMN.

DOUBLE STAR ORBITS.—In the *Astronomical Journal*, No. 378, Dr. See gives the complete list of the various double star orbits that he has computed and published in various journals. This is a useful compilation, and testifies to a considerable amount of industry, and exhibits his great interest in the subject. The "probable uncertainty" which he has attached to some of the elements is, however, very different from "the probable error," which is an arithmetical result, and has a definite meaning. The "limits of uncertainty" attached to the period and excentricity, give Dr. See's estimate of the degree of success with which he has handled incorrect and inadequate measures. Almost simultaneously with the appearance of Dr. See's paper comes, in *Ast. Nach.*, No. 3364, Dr. Doberck's results of his investigation of the orbit of γ Virginis, and it is scarcely necessary to remark, that he has had under review precisely the same observations that Dr. See has used. If Dr. Doberck is able to add one or two more recent observations, they have been made at a time when the companion is near aphelion, and have little influence on the orbit. Nevertheless, the period and excentricity differ more from the values that Dr. See has obtained than his assigned values of uncertainty. If, then, the treatment of the same observations, by experts in this class of computation, lead to sensibly different orbits, it is to be feared that new material, arising from the continued observation of stars that have been much less frequently measured than γ Virginis, will lead to still wider discrepancies.

ROTATION PERIOD OF JUPITER.—The movements of the various spots, &c., on the surface of Jupiter have been employed since the time of Schrœter (1787) for observing the period of rotation of the planet. During the last opposition two very marked spots have been specially persistent, and by means of one of them, the "Garnet" spot, Prof. A. A. Rambaut has made a new determination of the period (*Scien. Proc. Roy. Dublin Soc.*, vol. viii. p. 389). All the values hitherto found have demonstrated that the various parts of the surface rotate at different speeds, so this new value simply refers to the zone in which the spot is situated. This is the one having a zenographical latitude of $+13°$, the previously accepted period of which was 9h. 55m. 33·9s. The time was measured by taking the intervals between the transits of the spot over the fixed wire of the micrometer on the "South" equatorial. The time of central transit was taken as the mean of the preceding contact, bisection, and following contact of the spot. Corrections were applied for three sources of error which affect the result, viz.: (1) *Parallax*, (2) *velocity of light*, (3) *phase*. The final value of the rotation of this spot is 9h. 55m. $33·36 \pm 0·53$s., which agrees within one-fifth of a second with Schrœter's value.

TELLURIC LINES.—Prof. Ricco has been investigating the relative behaviour of the chief atmospheric lines of the solar spectrum under various observing conditions (*Mem. del Soc. Spettroscopisti Italiani*, vol. xxv. pp. 127–134, 1896). The lines particularly under discussion were 6868 (β), 6517, 6278 (α), 5943 (rainband), and 5800 (δ). Observing the spectrum with a direct vision spectroscope, the relative intensities of these lines were measured in three districts, Etna, Nicolosi, and Catania, with the sun at varying altitudes at each station. From the measured altitudes, the thickness of the absorbing stratum of air traversed was calculated for each observation. The tension of the aqueous vapour in the air was also recorded at the time each line was measured. On plotting the results graphically, and summing up the measures at each station, the general con-

clusion is that the intensities of all the lines were nearly proportional to the mass of air traversed. The lines 6868 (β), 6517, 6278 (α), and 5800 (δ) were practically of the same intensity, for equal masses of air, at all the three observing stations, showing that the presence of water-vapour had little or no influence on them, and indicating that their origin was most probably atmospheric oxygen. The *rain-band* line (5943), however, has, for equal masses of air, a much less (about one-third) intensity at Etna than at the other two stations. The mean vapour tensions at the three places, Etna, Nicolosi, and Catania, were as 3 : 7 : 10, so that this line 5943 is evidently due to aqueous vapour. The fact that when the observations are plotted the curves pass through or near the origin, indicates that the atmospheric oxygen and water-vapour are the sole causes of these telluric lines.

EXPLANATION OF SOLAR PHENOMENA.—In the June number of the *Astro Physical Journal*, J. Fényi discusses several new explanations of the various features of the solar surface, emphasising several physical facts, hitherto neglected, the consideration of which simplify the conception of the causes of the solar phenomena. He assumes that the prominences are masses of real matter in violent motion, and also that they are ejected into *free space*. The crucial point of his argument is that when a mass of hydrogen, say, is projected from the photosphere, and has passed through the chromosphere into free space, it is not diffused immediately, but takes a certain time, termed the *expansion interval*, which varies *directly* as the diameter of the mass, and is *inversely* proportional to the square root of the absolute temperature. By following out in detail the phenomena of eruptive prominences, he explains them all on this view, especially their unusual brightness and rapid dissolution. The *white* prominences he accounts for as being the expanded gaseous portions of former ordinary prominences, rendered visible by reflected sunlight. The *corona* he regards as being due to more distant masses of these gaseous materials, primarily ejected as prominences, the enormous length of some coronal streamers being no difficulty if they are admitted to be projected in free space. *Faculæ* will then be produced by these gaseous matters falling down on the photosphere again, their superior brightness being due to the heat generated during their fall, together with the actual radiation received from the sun itself. Their prevalence in sun-spot zones is explained if they are the consequence of eruptive prominences, which themselves favour these zones. This dispenses with the view that faculæ are projected prominences, and regards them as the *result* of prominence action. The much-disputed question of the reason of distorted spectral lines in prominences is greatly simplified by this explanation. If a mass of ascending gas as a prominence encounters a descending mass from a previous eruption, the resultant motion will in general be tangential to the solar surface, and will be capable of producing the enormous velocities in the line of sight which have been measured in prominence spectra, and which could not be explained as being the result of mere explosions from the photosphere.

NEW FORM OF APPARATUS FOR THE PRODUCTION OF RÖNTGEN RAYS.

SOME time in the month of March this year, after working with various forms of tubes, it occurred to the writer to abolish the glass vessel by converting the ordinary concave kathode into a nearly complete sphere, with the platinum anode at its centre. A simple experiment with a Jackson bulb proved that the rays from the anode could pass through the material of the kathode as they would through a similar piece of unelectrified aluminium placed outside the bulb. Hence it became fairly evident at the outset that the proposed plan would work to some extent.

Under the guidance of Prof. Lodge, and in his research laboratory, experiments were commenced. The first arrangement was a simple one. The sphere was made in two halves, one half of copper and the other of aluminium. The two halves were joined together with marine glue only. The anode was held in position by ebonite fixed in the copper hemisphere. A section of this simple arrangement is shown in Fig. 1. The section is drawn to scale, the diameter of the sphere being 2 inches. This early apparatus showed signs of success, and it was decided to invest in a larger sphere—one of $3\frac{1}{2}$ inches in diameter. The joints were now made much more carefully, and the apparatus so designed that it could be fitted together or taken to pieces in half an hour's time. The hemispheres of copper and aluminium were soldered together, but the joints (A and B, Fig. 1) were made by compressing indiarubber washers by means of suitably made screws. With this convenient apparatus the behaviour of various sizes and shapes of anodes was observed. In all the experiments a small thick plate of platinum, having a plane surface of about $\frac{1}{4}$ square inch, was reserved for that portion of the anode which received the kathode rays; the remainder of the anode was sometimes of aluminium and sometimes of copper. The various forms tried are shown in Figs. 2 to 8.

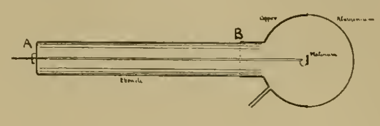


Fig 1

In Fig. 2 we have the simplest possible anode—the platinum plate alone. It is the same arrangement as that of Fig. 1, the only difference being that of dimensions. This form possessed an enormous resistance, so that only with low vacua could a current be made to pass through. For this reason the behaviour of this form was unsteady and its periods of activity very short. With higher vacua and greater potentials, no doubt this form would be more successful. Another form tried was that shown in Fig. 3. The anode here was very considerably enlarged by placing a circular plate of metal just behind the platinum, at a place where no kathode rays could fall on it. By this means the area of the anode surface was increased sixteen-fold approximately. The resistance was thereby much reduced, and it became possible to work at higher vacua. This form gave a more powerful and a considerably more uniform radiation than that of its predecessor.

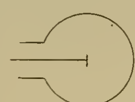

Fig 2

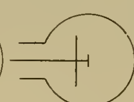

Fig 3

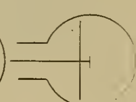

Fig 4

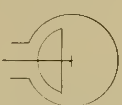

Fig 5

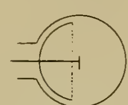

Fig 6

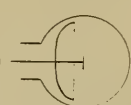

Fig 7

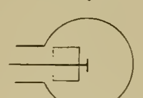

Fig 8

The next step was to increase still further the area of the anode (see Fig. 4). The anode now nearly filled the sphere. The result, however, was not so good, tending to show that the best size of anode is something less than Fig. 4, and greater than Fig. 2; but Prof. Lodge thinks that this is a question of the particular vacuum employed. Another differently-shaped anode was next tried. This was formed of a metallic hemisphere with a flat plate in front of it (see Fig. 5). The idea was to get all, or nearly all, of the electric discharge, and so possibly most of the kathode radiation also, to take place between the outer aluminium hemisphere and the anode. The idea probably is a crooked one; anyhow, this form proved less successful than others. The plate was next removed, and the hemisphere was replaced by a larger one, as in Fig. 6. For some unknown reason this form gave no radiation whatever, although the

vacuum was fairly high. The resistance, however, was low. The experiment was not really a successful one, for there arose some trouble from either small leakages or vapour pressures. The next form was Fig. 7. This gave really bright flashes on a sensitive screen, and the resistance was low. Still another form is that of Fig. 8. The anode now is a hollow cylinder with one end open. The total area of this anode is considerably greater than that of Fig. 3, but the latter gave much the more powerful radiation. It appears, therefore, that both the size and the shape of the anode have an important influence on the radiating power of the apparatus.

The form which gave the most powerful radiation was that of Fig. 3. This sent a powerful radiation through 3 feet of solid timber. The rays on emerging were received on a fluorescent screen made of about fifteen shillings' worth of potassium-platino-cyanide, and the area of which was 36 square inches. This screen was considerably affected by the rays after having traversed the 3 feet of timber, and gave sufficient light to see very small objects in. But the hand, when placed between the screen and the timber, cast no shadow whatever.

The next observation on the power of the radiation was to take the screen to a distance of 30 feet from the source. At this distance the bones of the hand could be seen, but not the flesh. Even the bones cast no deep and sharp shadows at this distance, not owing to lack of fluorescence—for the screen was really bright—but owing probably to the turbidity of the intervening 30 feet of air.

The source was afterwards placed in position at one end of the laboratory, and the screen taken to the opposite end, or rather to the end of the corridor leading to the laboratory—a distance of 62 feet from the source. Even here the screen fluoresced with some energy, but the hand was observed to cast no perceptible shadow. When this apparatus was working, there was no place within the large room where the screen did not fluoresce, the rays passing through masses of timber and tables with surprising penetration.

This experimental tube, however, with its rubber joints and ebonite insulation, is not a lasting concern. Although a good vacuum can be maintained for hours together when not in work, it will not last more than half an hour or so when in continuous use, after which more pumping is necessary. The current evidently produces some change in the rubber and ebonite, disengaging a gas which slowly destroys the vacuum.

In the final instrument the joints are of mercury, and the insulation of porcelain. The joints are first ground and polished, and then flooded with mercury. Except the porcelain, the entire apparatus can be made in the lathe, which is a great consideration. A longitudinal section of the instrument is given in Fig. 9. At the end of the porcelain is an arrangement for focusing, which can be manipulated while the instrument is working, so that a point source can be obtained definitely and easily by trial. This figure, which is reproduced from an early picture, has a spherical anode. This should be replaced by a circular plate resembling the anode of Fig. 3.

This last form of instrument, though designed in the middle of May, has not yet been built, owing to the delay in manufacturing the various parts. The parts are easily enough made, but manufacturers seldom care to attend to single articles except at their own convenience.

In conclusion it may be stated, though it is unnecessary to do so, that the instrument just described owes its existence to the teaching of Prof. Lodge. BENJAMIN DAVIES.

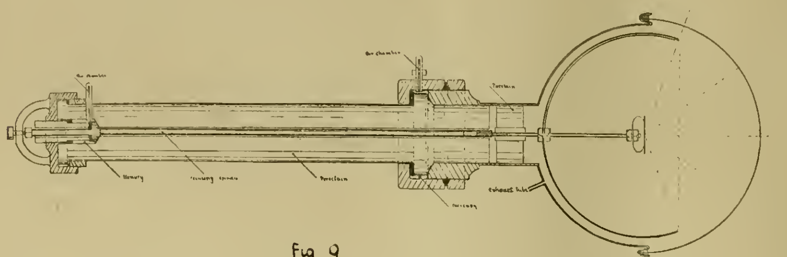

Fig 9

THE ROBOROVSKY EXPEDITION.

ROBOROVSKY and Kozloff, the two explorers who accompanied Prjevalsky in his last journeys, and for two years continued his work of exploration of Central Asia, are now back at St. Petersburg; and they have returned literally loaded with zoological, botanical, and geological collections, together with the results of meteorological observations and extensive surveys, as well as of numerous astronomical determinations. The chief interest of the collections will certainly be centred round the specimens of the wild horse (*Equus Przewalskii*) and wild camel which they have secured, as well as in the great numbers of new species of plants and insects which have been systematically collected by M. Kurilovitch, who stayed at well-chosen stations, while Roborovsky and Kozloff, mostly accompanied by one man only, made the most adventurous "excursions"—that is, journeys three and four hundred miles long—into the unknown highlands of the Nan-Shan. Great privations were endured by the two explorers during these journeys, which were made without guides, during the winter, when the thermometer stood at $-25°$ to $-35°$ C., and fearful snow-storms blew away the tent, while the sand borne by the wind sharply stung the travellers' frozen faces. These privations, of which the Russian travellers speak so light-heartedly, seem, however, to have ruined the health of the chief of the expedition, Roborovsky. And when the expedition made its last journey into the highlands which separate the Nan-Shan highlands from the valley of the Yellow River, Roborovsky, who had already endured pleurisy and erysipelas, was laid down with a stroke of paralysis, which deprived him of the use of all the right part of his body; while the Tangut robbers, who people these mountains, gathered in bands round the small encampment. The expedition was already at the western foot of the high snow-clad chain of peaks of the Alma-machin, which rise on the left bank of the famous bending of the Yellow River; a few days' journey only separated them from the yellow waters of the Hoang-ho; but in such conditions they were compelled to return—the Tanguts immediately taking advantage of the retreat to attack the caravan. They were only repulsed, Roborovsky writes, after "a great loss in men and horses."

Notwithstanding this failure, even the purely geographical results of the expedition, to say nothing of its scientific collections, are very important. From Lake Issyk-Kul the small party proceeded eastwards, exploring the highlands and the plateau of Yulduz, to Karashar, near Lake Denghiz, or Bagrach-Kul, and thence to Turfan and the oasis of Hami. Having now to cross the great desert of the Hashun Gobi, before reaching the Nan-Shans, Roborovsky and Kozloff took

two different routes: the eastern route, Hami to Sa-chou, and the western route, from Kurla to Lob-nor, and thence eastwards to Sa-chou, along the northern foot of the great border ridge, the Altyn-tagh. Two excursions made, for 150 miles, into the interior of the desert gave an insight into its physical features, flora and fauna. Moreover, before crossing the Gobi, the expedition explored in detail the remarkable Lukchun depression (in the south-east of Turfan), which was discovered by the brothers Grum-Grzimailo, and proved to be some 150 feet below the level of the ocean, although it is surrounded on all sides by high plateaus. Roborovsky established there a meteorological station, at which the barometer was observed for two consecutive years, and, accordingly, it may now be taken as certain that the surface of this depression is really from 150 to 300 feet below the sea-level.

Spending nearly one year in the Nan-shan highlands, the expedition has covered them with a whole network of surveys; so that when these surveys, as well as Obrucheff's researches are taken into account (as they are in a preliminary map appended to the *Izvestia* of the Russian Geographical Society), we see this region, almost entirely unknown three years ago, better explored now than many parts of Siberia. Where one ridge only was formerly drawn, we find on the new map a series of parallel ridges all running W.N.W. to E.S.E., intersected by high valleys, and attaining by their snow-clad peaks the heights of from 14,000 to 16,000 feet in the chains of Humboldt, Ritter, Da-sue-shan, and Alexander III.'s. The beginnings also have been made of a careful exploration of the Altyn-tagh, which was formerly known through Prjevalsky's and Littledale's journeys along its outer border.

It is pleasant to add that Roborovsky's health has much improved during the return journey, and that, on arriving in Russian Turkestan after a two years' absence, he could report "all well." The account of this journey will add several more important volumes to the scientific literature of Central Asia.

EVAPORATION.[1]

THE quantities of water added to the atmosphere daily by evaporation from the oceans and the continents constitute a fundamental consideration in meteorology; the quantities evaporated from cultivated fields, forests, and other forms of vegetation are equally important in agriculture, but as yet we have confessedly attained to only a very imperfect knowledge of this subject. Meteorologists have generally observed the amount evaporated from a small surface of water exposed either in the open air and sunshine, or else within such a shelter as is used for the open-air thermometer; lately a disc of moist paper has been substituted for the surface of water, as in the Piche evaporometer. Agriculturists, on the other hand, have made use of the lysimeter, which consists of a deep metallic box buried in the earth and having its open upper side flush with the surface of the ground. This box is filled with soil in which plants may or may not be growing, according to the object of the investigator. Record is kept of the amount of water or rain that is added to the lysimeter box from day to day, and also of the amount of water that drains from the bottom of the box. The difference between the two is adopted as the natural evaporation from the soil. The soil in the box may be kept very wet, to imitate a morass, or very dry to imitate a desert; the fineness of the soil may vary from coarse gravel to the finest silt.

If we desire the actual amount evaporated into the atmosphere, we must do more than record the results of the above forms of apparatus. The evaporating surface of water in the shaded thermometer shelter will indeed give up its moisture in proportion to the temperature of the water and to the velocity and dryness of the wind at its surface; but these three important factors have values so different out of doors from those within the shelter, that such records can, at the best, only give us a crude idea of the actual evaporation from surfaces in the open air. A great evaporation within the shelter, caused by a strong, hot, dry wind, may be accompanied by but little evaporation from the surrounding country if the latter be a desert of rock and gravel.

On the other hand, by means of the lysimeter, one may indeed determine directly the evaporation from soil of any character exposed to the natural outdoor conditions; but there then remains the difficult task of determining how much soil of each respective kind really occurs in the surrounding territory. In order, therefore, to determine the actual evaporation from land surfaces, one must observe a large number of lysimeters, and make an extensive minute survey of the country. The calculations incident to this latter method are very laborious.

The ordinary psychrometric observations give the dew-point or quantity of moisture in a small unit volume of air at any moment. If in the course of the day this quantity increases, we are not thereby warranted in concluding that the increase is due to a local evaporation; it may have been brought from a distance by the wind, or it may even have come down from the clouds as rain. If observations of dew-point are carefully made on all sides of a large field, over which a gentle wind is blowing, and if it should appear that there is a little more moisture in the air on the leeward side than on the windward side, one might conclude, provisionally, that this increase represented the quantity of moisture thrown by evaporation into the air as it gently moved over the surface of the field. But even this conclusion must be modified indefinitely by the consideration that in blowing across the field the wind does not move horizontally, but in a series of rolls and whirls by which the lower air in which we are observing becomes mixed with upper air, about whose moisture we know little or nothing.

In the midst of all these uncertainties it seems almost hopeless to attempt anything like an accurate determination of the moisture actually added to the atmosphere by evaporation from any extensive region of land or water; the question is far more complex than the determination of the evaporation from a reservoir of water, which latter problem is often attacked by the hydraulic engineers. Including the earth and its atmosphere in one comprehensive view, we may certainly say that the total annual evaporation from snow and ice, fresh water and salt water, must average the same as the total annual precipitation. We may even make an annual average for each continent, and say that the evaporation from the land plus the water that flows away in the rivers must equal the rainfall, and as the river discharge is frequently well known, we may, by subtraction, infer the evaporation. For the oceanic surface, on the other hand, the evaporation must equal the rainfall plus the river discharge from the continents.

The latest contribution to our knowledge of evaporation from land surfaces is published by Prof. E. Wollny, of Munich, at page 486, vol. xviii., of his "Forschungen." As the result of three years' continuous observations of five lysimeters and a neighbouring evaporometer, he concludes:

(1) That the quantity of moisture evaporated from the soil into the atmosphere is considerably smaller than that evaporated from a free surface of water.

(2) That the evaporation is smallest from naked sand, and largest from naked clay, whereas naked turf and humus or vegetable mould have a medium value.

(3) That the evaporation is increased to a considerable extent by covering the ground with living plants.

As the result of a minute analysis of the complex relations between the evaporation and the meteorological elements, on the one hand, and the physical features of the soil, on the other, Dr. Wollny further concludes as follows:

(4) Evaporation is a process that depends both upon the meteorological conditions and on the quantity of moisture contained by the substratum of soil.

(5) Among the external circumstances temperature is of the greatest importance, inasmuch as, in general, evaporation increases and diminishes with it; but this effect is modified according as the remaining factors come into play, and in proportion to the quantity of water supplied by the substratum.

(6) The influence of higher temperature is diminished, more or less, by higher relative humidity, greater cloudiness, feebler motion of the wind, and a diminished quantity of moisture within the soil, whereas its influence increases under opposite conditions. On the other hand, low temperatures can bring about greater effects than high temperatures if the air is dry, or the cloudiness small, or the wind very strong, or if a greater quantity of water is present within the evaporating substance.

(7) For the evaporation of a free surface of water, or for earth that is completely saturated with water, the important elements are—first the temperature, next the relative humidity

[1] Prof. Cleveland Abbe, in the U.S. *Monthly Weather Review*.

of the air, and then the cloudiness, direction and velocity of the wind; whereas, for the ordinary moist earth, no matter whether the surface is naked or covered with living plants, it is the quantity of rain upon which the soil depends for its moisture that is the important additional consideration. The effects of the external elements on evaporation become less important, as explained in paragraph 5, in proportion as the precipitation is less and as the soil is more completely dried out by the previous favourable weather, and *vice versa*. For these reasons the rate of evaporation from a free surface of water not infrequently differs largely from that from the respective kinds of soil.

(8) Free surfaces of water, and soils that are continuously saturated, evaporate into the atmosphere on the average more water under otherwise similar circumstances than soils, whether naked or covered with plants, and whether watered artificially or naturally. Only at special times, viz. when the influence of the factors that favour evaporation is most intense, when the plants are in the most active period of growth, and when the soil contains a large percentage of water, can the land that is covered with plants show a larger evaporating power than the free-water surface.

(9) When a soil that is not irrigated is covered with plants, it evaporates a far greater quantity of moisture than when the surface is bare. In the former case the evaporation can not exceed the quantity received by the soil from the atmosphere before or during the period of growth. Swampy lands and those that are well irrigated, as also free surfaces of water, can, under circumstances favourable to evaporation, sometimes give to the atmosphere a greater quantity of water than corresponds to the precipitation that occurs during the same time.

(10) The evaporating power of the soil is, in itself, dependent upon its own physical properties; the less its permeability for water, or the larger its capacity for water and the easier it is able to restore by capillarity the moisture that has been lost, by so much the more intensive is the evaporation. For this reason the quantity evaporated increases with the percentage of clay and humus in the soil, whereas it diminishes in proportion as the soil is richer in sandy and coarse-grained materials.

(11) Soil that is covered with plants loses by evaporation so much more water in proportion as the plants are better developed, or stand thicker together, or have a longer period of vegetation, and *vice versa*.

In conclusion, Wollny repeats that the use of apparatus giving the total evaporation from free-water surfaces does not respond to the needs of the agriculturist [and we may add of the meteorologist], but that instruments must be used for measuring the evaporation from masses of earth that are wet with rainfall only, and free from stagnant wet soils. Lysimeters are recommended having a section of one-tenth of a square metre and a depth of soil one-half of a meter, and set out in the open air, sunk flush with the surface of the ground, and arranged so as to be easily weighed at any moment, and so that the drainage water can easily be measured.

The foregoing results of Wollny's laborious observations confirm us in the general conclusion that the quantity of water actually evaporated from a large surface of land, such as a definite watershed maintaining a single river, can only be determined by the following considerations. The quantity of water contained in the soil at the end of any given period in excess of what it contained at the beginning, plus the water that is carried off by drainage and river flow, plus whatever is evaporated into the atmosphere either directly or through the crops and forests, must equal the rain and irrigation water added to the soil during that time. As the soil content of water, the riverflow and drainage, and the rainfall can be severally determined by direct observation far better than the evaporation, the latter is to be determined by taking the difference between the rainfall and all other sources of loss or consumption.

LONDON UNIVERSITY COMMISSION BILL.

REFERENCE was made in our issue of July 9, to the Bill introduced by the Duke of Devonshire in the House of Lords, for the purpose of appointing a statutory Commission to make further provision with respect to the University of London. The Bill reads as follows:—

Whereas the Commissioners appointed to consider the draft charter for the proposed Gresham University in London, have by their report made recommendations with respect to the reconstitution of the University of London, and to the appointment of a statutory Commission for that purpose:

Be it therefore enacted by the Queen's most Excellent Majesty, by and with the advice and consent of the Lords Spiritual and Temporal, and Commons, in this present Parliament assembled, and by the authority of the same, as follows:—

I. *Appointment of Commissioners.*—(1) There shall be a body of Commissioners styled the University of London Commissioners, and consisting in the first instance of the following persons [names not yet announced].

(2) If and whenever any vacancy occurs among the Commissioners, it shall be lawful for Her Majesty the Queen to appoint a person to fill the vacancy; but the name of every person so appointed shall be laid as soon as may be before both Houses of Parliament.

(3) The Commissioners may, with the consent of the Treasury as to number, appoint or employ such persons as they may think necessary for the execution of their duties under this Act, and may remove any person so appointed or employed.

(4) There shall be paid to any person so appointed or employed such remuneration as the Treasury may assign, and that remuneration and all expenses of the Commissioners incurred with the sanction of the Treasury in the execution of this Act shall be paid out of moneys provided by Parliament.

II. *Duration and proceedings of Commissioners.*—(1) The powers of the Commissioners shall continue until the end of the year one thousand eight hundred and ninety-seven, and no longer; but it shall be lawful for Her Majesty the Queen, from time to time, with the advice of Her Privy Council, on the application of the Commissioners, to continue the powers of the Commissioners for such time as Her Majesty thinks fit, but not beyond the end of the year one thousand eight hundred and ninety-eight.

(2) The Commissioner first named in this Act shall be the Chairman of the Commissioners; and in case of his ceasing from any cause to be a Commissioner, or of his absence from any meeting, the Commissioners present at each meeting shall choose a chairman.

(3) The powers of the Commissioners may be exercised at a meeting at which three or more Commissioners are present.

(4) In case of an equality of votes on a question at a meeting, the chairman of the meeting shall have a second or casting vote in respect of that question.

(5) The Commissioners shall have a common seal which shall be judicially noticed.

(6) Any act of the Commissioners shall not be invalid by reason only of any vacancy in their body; but if at any time, and as long as, the number of persons acting as Commissioners is less than four, the Commissioners shall discontinue the exercise of their powers.

III. *Powers and duties of Commissioners.*—(1) The Commissioners shall make statutes and regulations for the University of London in general accordance with the scheme of the report hereinbefore referred to, but subject to any modifications which may appear to them expedient after considering any representations made to them by the Senate or Convocation of the University of London, or by any other body or persons affected.

(2) In framing such statutes and regulations, the Commissioners shall see that provision is made for securing adequately the interests of collegiate and non-collegiate students respectively.

(3) Statutes and regulations made under this Act shall have effect notwithstanding anything in any Act of Parliament, charter, deed, or other instrument.

IV. *Approval of statutes and regulations.*—(1) When any statute or regulation has been made by the Commissioners, a notice of its having been made, and of the place where copies of it can be obtained, shall be published in the *London Gazette*, and the statute or regulation shall be laid as soon as may be before both Houses of Parliament, and shall not be valid until it has been approved by Her Majesty the Queen in Council.

(2) If either House of Parliament within forty days, exclusive of any period of prorogation, after a statute or regulation has been laid before it, presents an address praying the Queen to withhold her assent from the statute or regulation, or any part thereof, no further proceedings shall be taken on the statute or regulation, or on the part thereof to which the address relates, but this provision shall be without prejudice to the making of a new statute or regulation.

(3) The Senate or Convocation of the University of London, or any other person or body directly affected by any such statute or regulation, may, within thirty days after the notification thereof in the *London Gazette*, petition Her Majesty in Council to withhold her approval of the whole or any part thereof.

(4) Her Majesty in Council may refer any such petition to a committee of the Privy Council, with a direction that the committee hear the petitioner personally or by counsel, and report specially to Her Majesty in Council on the matter of the petition.

(5) Thereupon it shall be lawful for Her Majesty by Order in Council either to declare her approval of the statute or regulation in whole or in part, or to signify her disapproval thereof in whole or in part, but any such disapproval shall be without prejudice to the making of a new statute or regulation.

(6) The costs of any petition under this section may be regulated by the committee to which the petition is referred.

V. *Power to amend statutes and regulations.*—After the expiration of the powers of the Commissioners the Senate of the University shall have power to make statutes and regulations for altering or supplementing any of the statutes or regulations made by the Commissioners. Provided as follows :—

(1) A statute made under this section shall be subject to the provisions of the last foregoing section, with the substitution only of the Senate for the Commissioners ;

(2) A regulation made under this section shall be invalid so far as it is inconsistent with any statute made under this Act and for the time being in force.

VI. *Short title.*—This Act may be cited as the University of London Act, 1896.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A DESPATCH (says the *Board of Trade Journal*) has been received at the Foreign Office from Mr. Martin Gosselin, Her Majesty's Chargé d'Affaires at Berlin, stating that a Government chemical dyeing school has recently been opened at Crefeld, which has cost about £20,000, exclusive of the machinery and fabrics, which have for the most part been presented by private manufacturers. The school contains laboratories for research and educational purposes, as well as a complete collection of dyeing machinery, and an exhibition showing the result of different processes.

THE following are among recent announcements :—Dr. Franz Boas to be lecturer on physical anthropology in Columbia University ; Dr. Arthur Allen to be professor of psychology and pedagogy in the Ohio University ; Dr. Bauer, professor of mineralogy at Marburg, to be Privy Councillor ; Dr. H. Biltz to be extraordinary professor of chemistry at Greifswald ; Dr. Linde, professor of physics in the Munich Technical High School, to be Ph.D. *honoris causa* of Gottingen University.

PLANS have been filed for the buildings of Barnard College in New York City. Three halls have been provided for. The central one is named Milbank Hall, in honour of the donor, Mrs. Anderson, *née* Milbank, and will cost 160,000 dols. Opposite the grounds of Columbia University will be Brinkerhoff Hall, costing 132,000 dols., the gift of Mrs. Brinkerhoff. The third hall for which the plan provides will correspond to Brinkerhoff Hall. Funds are not yet provided for it, nor a name assigned.

SCIENTIFIC SERIALS.

American Journal of Science, July.—Lecture experiment with liquid carbon dioxide, by C. Barus. The passage from the liquid into the gaseous state should be shown in full daylight, the tube containing the liquid being placed vertically in a wooden trough closed by plate-glass at both ends. This insures safety, and gives more light than a water-bath. The image of the tube is thrown upon a screen. Two different focal lines are obtained, one for the gas, the other for the liquid. Contrary to what might be expected, the one does not pass continuously into the other, that for the gas being always virtual, and that for the liquid real.—Percussion figures on cleavage plates of mica, by T. L. Walker. These figures, produced by a blow on the centre of a hexagonal plate with a blunt needle, have been described as being six-rayed stars with the rays at 60° to each other. Accurate measurements show that the angles may vary from 53° to over 63°, according to the kind of mica employed.—The seven-day weather period, by H. Helm Clayton. To extend the investigation of the seven-day weather period beyond the area of the United States, three stations were selected in the Arctic region, five in Europe, two in Asia, two in Oceania near the equator, three in middle South America, one in Mauritius, and one in Australia. The periods investigated were those of 7 days 6·43 hours, 6 days 3·95 hours, and 5 days 10·8 hours. Particular attention was given to a compilation of barometric minima at these stations during the last fifteen years. The results show that, on the average, twice in a period of 7 days 6·43 hours in America, and three times in Europe, waves of barometric minima, or storms, tend to begin near the poles, and sweep across the continents. There is a tendency at every station for the days of maximum frequency to remain on the same days of the period throughout the year.—The hydrology of the Mississippi, by J. L. Greenleaf. This is a valuable and interesting paper dealing with the drainage areas, rates of flow, and rainfall over the tributaries of the great American river. It is illustrated by diagrams representing the various factors in a concise and lucid manner. The largest drainage area is that of the Missouri. Then follows the Ohio, the Arkansas, and the Red River. Of these, the Missouri has the most striking peculiarities. Its drainage area has an average rainfall of 19·6 inches per annum. Although in flood it is a mighty torrent, its average volume is very poor considering its enormous drainage area of 527,700 square miles. Only 12 per cent. of the rainfall finds its way into the river. The rest is absorbed and evaporated by the extensive prairies. In the Ohio area the proportion is 30 per cent., and since the annual rainfall is 43 inches, it is not surprising that its discharge exceeds that of the Missouri. Near the Mexican Gulf we have the Yazoo and St. Francis Rivers, which carry off 70 per cent. of their rainfall, owing to its being quickly absorbed by the sandy soil, or stored in the swamps. There are other admirable diagrams showing the growing volume of water as each tributary enters, and giving the whole life-history of the river system in a very attractive shape.

Wiedemann's Annalen der Physik und Chemie, No. 6.—Electrolysis of water, by A. P. Sokolow. Helmholtz applied his theorem of free energy in thermodynamics to electrolysis, and concluded that the E.M.F. necessary to electrolyse water depends upon the density of the hydrogen and oxygen at the electrodes, and that when the liquid is free from gas the necessary E.M.F. may closely approximate to zero. The author endeavoured to find a more rigorous experimental proof of this conclusion than has hitherto been obtained. This was done by constructing a voltameter with platinum electrodes in which separate platinum wires were fused in close to the electrodes. Any polarisation of the latter due to a current, if leading to the formation of gas, would be gradually transferred to the wires through the separating liquid. This was found to be the case, and dissociation was obtained with E.M.F.s of a few hundredths of a volt.—Loss of energy in magnetisation by oscillatory condenser discharges, by Ignatz Klemenčič. Hysteresis and other losses have so far only been investigated with about a hundred oscillations per second. The author experimented with condenser discharges up to 2000 per second in order to obtain an approximate idea of the action of Foucault currents and hysteresis in iron and nickel at higher frequencies. The method used was that of discharging a condenser and interrupting its discharge at a certain stage by a dropping weight. This made it possible to determine the damping of the oscillations in a simple coil and in a coil with an iron or nickel core respectively. The results showed that even in thin iron wires the loss of energy was chiefly determined by the Foucault currents. The losses due to hysteresis in soft iron were considerably greater than those calculated from the hysteresis curves at lower frequencies. For steel and nickel, however, the losses were about the same.—On magnetic irregularity and the annealing of iron and steel, by A. Ebeling and E. Schmidt. Annealing, if done uniformly, may be sometimes useful ; but if not uniform, it may be detrimental to magnetic homogeneity. The most uniform material is obtained by careful fusion. Wrought iron is not made magnetically uniform by annealing.—Transparency of bodies for Röntgen rays, by O. Zoth. This was determined by comparing them with a tinfoil scale containing grades of various thicknesses. The transparency of alcohol compared with tin was 600, that of water 300, cork 2450, ebonite 150, plate-glass 29, magnesium 36,

aluminium 25, lead 0·29, gold 0·28, and platinum 0·25. The author also found a slight difference between the transparency of solid substances and their powders, which shows that there is some reflection or refraction. Loose powder was even less transparent than pressed powder.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 21.—"Note on the Larva and Post-larval Development of *Leucosolenia variabilis* H. sp., with Remarks on the Development of other Asconidæ." By E. A. Minchin.

The larva of *Leucosolenia variabilis* is an amphiblastula of a primitive type, transitional in many respects between the larva of the lower Ascons and the amphiblastula of the Sycons. It has an anterior ciliated, and a posterior non-ciliated pole, but when first hatched the ciliated pole is relatively very large, and the non-ciliated cells are few in number. During the free-swimming larval period the non-ciliated cells increase through their numbers being recruited from the ciliated cells, of which those situated more posteriorly become modified into granular cells after passing through an intermediate stage. In addition to anterior ciliated cells, posterior granular cells, and the equatorial zone of intermediate cells, the larva has cells of a fourth kind, placed in the centre of the body, immediately behind the minute central cavity, which contains gelatinous matter and is surrounded laterally by a ring of pigment lodged in the inner ends of the ciliated and intermediate cells. The central cells, together with the pigment, appear to constitute a larval organ, perhaps sensitive to light, which is lost at the metamorphosis.

The larva swims for 36-48 hours and fixes by the anterior pole. The granular cells grow round the ciliated cells, and the former become the dermal layer, the latter the gastral layer. At first the dermal layer forms an epithelium of a single layer, which becomes two-layered by immigration of certain of its cells. The dermal cells which remain on the surface secrete each a single monaxon spicule; those which migrate inwards arrange themselves into groups, and secrete the tri- and quadri-radiate spicules. While these changes are taking place in the dermal layer, a central cavity has appeared, round which the gastral cells arrange themselves in a columnar epithelium and gradually assume the characters of collar cells. At one spot the cavity is not lined by gastral cells, but by dermal cells only; it is here that the osculum is formed about the sixth day of fixation.

In the other Ascons investigated—*L. cerebrum*, *L. coriacea*, and *L. reticulum*—the larvæ are oval ciliated blastulæ in which an inner mass of cells is formed by modification and subsequent immigration of certain of the ciliated cells. In *cerebrum* and *coriacea* the immigration appears to be multipolar; in *reticulum* it takes place from the posterior pole, and thus affords a transition to the above-described larva of *variabilis*. If the cavity of the larva of *reticulum* be imagined reduced to the extent to which this has occurred in *variabilis*, then the modified cells at the hinder pole, instead of migrating inwards, must remain where they are, and as more ciliated cells become modified around them, a type of larva is obtained with ciliated cells anteriorly, intermediate cells laterally, and non-ciliated cells posteriorly, as in *variabilis*. This homology is further borne out by the fact that in all these larvæ the inner mass becomes the dermal layer, and the ciliated cells become the gastral layer, as the result of changes in position which take place at the metamorphosis. The post-larval development of the layers is similar to that described for *variabilis*.

When the development of *L. variabilis* is compared with that of Sycon as described by Schulze and Metschnikoff, it is seen that the only difference between them lies in the periods at which the events take place. In Sycon the larva, while still in the maternal tissues, undergoes changes which in *variabilis* take place during the free-swimming period, and the dermal cells surround the gastral cells before fixation in Sycon, instead of after fixation, as in *variabilis*.

The primitive larva of Calcarea was probably a ciliated blastula, in which an inner mass, the future dermal layer, was formed by modification and immigration of certain of the cells.

The immigration of cells from the dermal layer to form the triradiate spicules is precisely similar to what occurs in the adult whenever new spicules arise. Hence this process is not to be regarded as one of blastogenetic, but of histogenetic significance. In other words, sponges are to be regarded as two-layered animals, and not as possessing a mesoderm.

June 18.—"On Fertilisation, and the Segmentation of the Spore, in *Fucus*. By Prof. J. Bretland Farmer and Mr. J. Ll. Williams.

An account was given of an investigation into the mode of formation of the oospheres, of their fertilisation by the antherozoids, and of the germination of the resulting spores in various members of the Fucaceæ, special attention being paid to the protoplasmic structures therein concerned. The chief points were illustrated by lantern-slides from photomicrographs.

In order to study the fertilisation and germination stages, diœcious species were selected, and the male and female plants were kept in separate dishes, covered over so as to prevent drying up. This method gave far better results than those more usually advocated. On the appearance of the extruded sexual products, the female receptacles were placed in sea water, and after the complete liberation of the oospheres, a few male branches with ripe antherozoids were first placed in a capsule of sea water until it became turbid owing to their number. If on examination the antherozoids proved to be active, small quantities were added to the vessels containing the oospheres. The latter were then fixed at intervals of five minutes during the first hour, and then at intervals of fifteen minutes, up to six hours after the addition of the antherozoids. After that, samples were killed at longer intervals up to three days, and this was continued till we had material fixed at all stages for the first fortnight. At first sea water was used in which to keep the embryos growing, but a proper solution of Tidman's sea salt was found to answer quite as well. A large number of fixing reagents were tried, but Flemming's solution diluted with sea water gave the best results. Many reagents in common use proved utterly worthless. In embedding the tissues and spores in paraffin, previous to cutting them, it is important not to allow the temperature to rise above 50° C.

When an oogonial nucleus is about to divide, it first becomes slightly, then very much, elongated so as to resemble an ellipse. Fine radiations are seen to extend from the two ends into the surrounding cytoplasm. The latter is at first tolerably uniformly granular, but as the radiations around the polar areas increase, these regions become cleared altogether of the granules which then become massed outside them. The nucleus rapidly becomes more spindle-shaped, and its chromatic elements are chiefly grouped near each pole, leaving a clear space about the equator in which the nucleolus is situated.

The polar radiations continue to increase and the nucleus to lengthen, until the entire structure recalls the figure of a dumb-bell, in which the nucleus answers to the handle, and the radiation areas to the knobs. If the radii be traced outwardly, they are seen to terminate either in the frothy protoplasm, on the angles where the foam walls meet, or on the large granules which surround the cleared areas and are embedded in the foam. No structures were seen which could *certainly* be identified as centrosomes, although bodies suggestive of them were often observed; but these proved to be so variable in size and position, as well as in number, that it appeared impossible to attach any special significance to them.

The achromatic spindle is remarkable, inasmuch as it is intranuclear. The chromosomes were too minute to admit of their development being satisfactorily studied, but in all the *oogonial* spindles the number was estimated as *ten* when seen in profile. After the delimitation of the oospheres, some of them were observed to contain more than one nucleus. This is an abnormal feature, and the non-recognition of this fact has led to mistaken views in the past. When the oospheres are extruded, and come to lie free in the water, they swell somewhat, and are turbid with granules, which are very abundant in the cytoplasm. About five minutes after the mixing of the sexual cells, the antherozoids are found to have slipped into many of the oospheres. The act of penetration was not observed, but, in a number of cases, the antherozoid could be recognised within the oosphere, before its final fusion with the nucleus of the latter. It is a roundish, densely staining body, and, unlike the majority of animal sperm cells as yet described, no system of radiations are associated with it when in the egg. Judging from the short period of time elapsing between its penetration of the surface of the oosphere and its arrival at the exterior of the female nucleus, it must pass through the intervening cytoplasm with great rapidity. It then becomes closely appressed to the nucleus,

and is about as large as the nucleolus of the latter. It rapidly spreads over a part of the female nucleus as a cap, and it presents a less homogeneous aspect than before. Both it and the female nucleus assume a granular character, which is probably to be interpreted as representing a coiling and looping of the linin of the respective nuclei. Finally the two nuclei coalesce, and the original components can no longer be distinguished. Complete fusion may be effected in less than ten minutes after the addition of the antherozoids to the water.

A delicate pellicle is meanwhile formed around the periphery of the oosphere, which is thus easily distinguished from the unfertilised oospheres, in which such a membrane is wanting. The texture of the cytoplasm also changes, and tends to assume a more definitely radiating character, the lines starting from the nucleus as a centre.

After fertilisation, the cells rest for a long interval of time—commonly about twenty-four hours—before they begin to segment. The principal changes which occur during the interval are, first, in the rapid increase in the thickness of the peripheral cell wall, and, secondly, in the more regular arrangement of structure exhibited by the protoplasm. The alveolar or foam character is extremely clear, and the chromatophores, which by this time have become very prominent, are noticed to be situated in the angles formed by the convergence of the foam walls; they are often bent and otherwise distorted, and so accommodate themselves to the structural condition of the foam.

The first segmentation-division resembles, in a general way, the oogonial nuclear divisions already described. The achromatic fibrils forming the polar radiations are clearly seen to be attached to the foam-like structure of the cytoplasm, and, in some cases, insensibly to pass into it. At other times fibrils end on granules (or, perhaps, on the protoplasmic lining of the granules), and sometimes again a fibril may fork, and its branches end either on granules or on the foam angles. The interpolar portion of the spindle is intranuclear, and the chromosomes, when arrayed at its equator, are seen to be *twice as numerous* as those in the oogonial spindles. This doubled number is maintained throughout the thallus divisions, and the reduction in their number only occurs in connection with the actual differentiation of the sexual cells. The theoretical conclusions to be drawn from these facts were briefly indicated by the authors.

"Phenomena resulting from Interruption of Afferent and Efferent Tracts of the Cerebellum." By Dr. J. S. Risien Russell, Research Scholar to the British Medical Association.

Continuing his researches into the functions of the cerebellum, the author has directed his attention to the effects of dividing one inferior peduncle of this organ. He finds that in the disorders of equilibration which result, the direction of rotation is towards the side of the lesion, or, in other words, if, as was always the case, the left peduncle was divided, the animal rotated like a right-handed screw entering an object.

The disorders of motility which result from such a lesion correspond exactly with those observed after ablation of one lateral half of the organ, and consist in defective movement in the limbs on the side of the divided peduncle, and of the posterior limb of the opposite side. It is suggested that these effects may result from the interruption of afferent impulses passing to the cerebellum, rather than from the cutting off of efferent impulses from the cerebellum to the spinal centres. The interruption of similar impulses are held responsible for the displacement of both eyes downwards and to the opposite, a displacement which also resulted after removal of one lateral half of the cerebellum.

Spasm, which was easily detected in the back and neck muscles on the side of the lesion, causing incurvation of the vertebral axis to that side, alone furnished any satisfactory information in support of the view that the cerebellum exerts an inhibiting influence on the spinal centres; but the tendon reflexes afforded no satisfactory information on this point.

Sensibility was blunted on those extremities in which motor power was defective, a point in favour of the author's previous contention that the cerebellum is concerned with sensory as well as with motor processes.

The excitability of the cortex of the opposite cerebral hemisphere to the Faradic current was less than that of the hemisphere on the same side as the divided peduncle, a result which strengthens the view that one lateral half of the cerebellum exerts a control on the opposite cerebral cortex, as was suggested by certain results previously obtained by the author, and which further points to the possibility that the cerebellum is in its turn inhibited by afferent influences which reach it from lower centres. This view is made still more probable by the remarkable results obtained by the intravenous injection of absinthe after division of one inferior peduncle of the cerebellum, for during the otherwise general convulsions which resulted, there was a complete absence of convulsions in the muscles of the anterior extremity on the side of the lesion, and a diminution of the convulsions in the muscles of the posterior extremity of the same side.

These results were supplemented and controlled by other experiments in which the lateral tracts of the medulla oblongata were divided on one side without injury to the pyramid, by others in which the posterior columns and their nuclei were divided on one side, and by others in which partial hemisection of the medulla was performed, including all the structures on one side with the exception of the pyramid.

Balland.—On the treatment of such diseases as gout and diabetes by high frequency currents, by M. Vigouroux.—On the results furnished by orchitine in the treatment of leprosy, by M. Bouffé.

PHILADELPHIA.

Academy of Natural Sciences, June 23.—Rev. H. C. McCook reported a series of observations on the California trapdoor spider, *Ctenisa Californica*, made by Dr. Davidson, who has been able to determine the time required for the construction of the burrow in confinement, and other matters connected with the life-history of the animal. It has taken ten hours to construct the nest with its hinged door, another spider having made a hole large enough to conceal itself in two hours. The method of digging was the same in the main as that described by Dr. McCook for the tarantula. The young, when they emerge, at once build their own miniature nests, which are renewed every spring until they reach the full size. Based on the study of a Lycosid, the speaker had predicted that the enemy of the trapdoor spider would be found to be a diurnal wasp. Dr. Davidson had established the fact that such is the case, and that the attacking species is *Parapompilus planatus*, Fox.—Mr. H. C. Mercer made a report on his recent exploration of certain caves in Tennessee, which he had been able to prosecute under the patronage of the University of Pennsylvania, mainly through the liberality of Dr. William Pepper. In Zirkel's cave on Dumpling Creek, Jefferson County, Tennessee, crusts of breccia projected from the walls and hung from the roof. From this material the teeth of the tapir, peccary, &c., projected, while in the cave below were found bones, nuts, two pieces of Indian pottery and fragments of mica, probably indicating Indian burial cave. There were therefore two ages indicated : one ancient, by the breccia, and the other, the cave earth, comparatively recent. All the fossil remains belonged to the breccia, and there was no association between them and the indications of human life. Another cave on the Tennessee River, under Lookout Mountain, Hamilton County, Tennessee, presented a floor of two layers, the black top one, of three or three and a half feet in thickness, composed of Indian remains, and another of yellow earth containing a few animal remains but no indication of human existence. Mylodon and Tapirus fragments, found some time ago close to the bottom of the upper layer, had probably been scraped up from the lower. Neither, therefore, did this cave present any certain data for the advancement of the date of man's antiquity. On the contrary, the evidence supported the belief that pleistocene or palæolithic man had not existed in that region. On penetrating the forbidden entrance of Big Bone Cave, near Caney Fork River, Van Buren County, Tennessee, he had found, nine hundred feet in, the bones of *Megalonyx* still bearing articular cartilages. Fragments of torches were found beneath the sloth bones, probably buried by burrowing rats. Prof. E. D. Cope commented on the fossil bones collected in the caves described by Mr. Mercer. The presence of cartilages on the *Megalonyx* bones indicated for them an age certainly not more remote than the existence of man on this continent. Other bones belonging to young individuals were larger than corresponding ones found at Port Kennedy, indicating the validity of the two species: *Megalonyx Wheatleyi* and *M. Jeffersonii*. Mr. Mercer had also collected remains of fifteen or twenty species of birds, six fishes, one batrachian, four tortoises, one rattlesnake, and nineteen mammals. The special value of Mr. Mercer's careful work was commented on. The peccary is found in Zirkel's cave, although no trace of it appears in the Lookout Mountain cave. Several undescribed species were indicated.

INDUSTRIAL PHOTOMETRY.

A Treatise on Industrial Photometry, with special application to Electric Lighting. By A. Palaz, Sc.D. Translated from the French by G. W. Patterson and M. R. Patterson. Pp. x + 322. (London: Sampson Low and Co., Ltd.)

IT is remarkable, considering the importance of artificial methods of illumination, that there is so little literature dealing with the subject of light measurement treated from an industrial point of view. The introduction of electric lighting, and still more recently the success of the incandescent gas system, have aroused in the public a demand for more powerful methods of illumination than formerly were found to satisfy. But the problems involved in the economical arrangement of artificial light sources are very little understood. The scientific aspect of the subject has, indeed, hardly advanced at all during the last few years. Electrical engineers have made great efforts to increase by one or two per cent. the efficiency of dynamos intended for electric lighting purposes; but the study of arrangements of lamps and reflectors, to produce the best effect, has been almost ignored, with the result in many cases of losing quite half the usefulness of the light. There are in fact many problems involved in the economical distribution of lights, the importance of which is little recognised, and the solution hardly yet discovered. They are not to be found in text-books, and are only alluded to in isolated papers scattered about in the technical journals. The present work is a valuable compilation of facts and experiments obtained from the best technical authorities; and is the only book we know of in which this information can be obtained. The matter has not been hastily put together, since the book is a development of a long series of articles published by the author in *La Lumière Électrique* in 1887, and now enlarged and brought up to date.

The work is divided into six chapters, the first of which is introductory and deals with the principles of the subject. It contains some useful information, but is disfigured by an unfortunate choice of terms. The *candle-power* of a source of light, or the quantity of light emitted by it per unit solid angle, is here denoted by the objectionable term *total intensity*. Now the candle-power of a candle, like the horse-power of a horse, may vary from time to time; but whatever the vagaries of a so-called standard candle, the term candle-power is quite scientific. To replace this simple, accurate, and much-used expression by a vague, misleading, and unknown term, is most unfortunate, especially since, with all ordinary light sources, the candle-power varies with the direction considered, and one has to try and realise what the mean-spherical-"total"-intensity of a light source may be. The translators have, in fact, reproduced too literally the author's word intensity, which turns up over and over again in quite a needless fashion, as for instance in the phrase *intensity of illumination*, which is used to denote the quantity which English writers generally denote by the single word *illumination*. It is a great pity to make this latter word synonymous with quantity of light, as is done in this book. The ordinary idea conveyed in the assertion that an area is well illuminated, is not that there is a large quantity of light falling upon it, but that the quantity falling on it *per unit area* is considerable. The word illumination when used scientifically should correspond with this popular, and also precise, meaning. It should denote the density of the flux, not the flux itself, as the translators have unfortunately made it do.

The second chapter, on photometers, is a most valuable one. It is the longest in the book, and, like all the other chapters, is well illustrated. Photometers are divided into six classes, and over forty are described. The information given is by no means confined to instrumental details, for matters connected with the theory and practical use of the apparatus receive a good deal of attention. For instance, many useful details of various modes of making Foucault and Bunsen screens are given, and the theory of the Bunsen photometer is very fully discussed. It is remarkable how complicated this theory becomes when examined, and it does not appear that the theory given is too elaborate. As a matter of fact the optical properties of diffusing screens have been very little studied, and what has really been done in this direction seems to show that they cannot be treated in so simple a manner as is here assumed. This chapter is a useful summary of the different varieties of photometers, and leaves little to be desired. Naturally some of the instruments alluded to are of small value, while others depend on principles of a debatable character. This is especially the case in connection with heterochromatic photometry, a subject on which opinions seem to differ widely. The author is inclined to dissent from Helmholtz' assertion that "of all the comparisons effected by the aid of the eye between the intensities of different sorts of composite light, there is not one which possesses an objective value independent of the nature of the eye." Apparently many disagree with this view, since several photometers are described in which the judgment of the eye is only appealed to after the contending lights have been subjected to elaborate processes, which make it doubtful whether the decision obtained has any reference to their illuminating powers. Helmholtz' view seems to be the true one after all, and in fact it is difficult to dispute it in view of the property of the eye known as Purkinje's phenomenon, according to which the ratio of the illuminating powers of two lights of different composition varies if the intensity of each light is reduced in the same proportion. There is, no doubt, something to be said for adopting methods of comparison independent of the eye, owing to the fact that not only do two observers differ from one another, but a single observer obtains different results at different times. This, however, is largely a matter of practice, and we believe that Captain Abney, and others who have worked much at colour photometry, make little of the difficulty of judging when two illuminated surfaces of different colours are equally luminous. Certainly some of the photometers described here seem of doubtful value, in spite of the skill shown in their design, owing to the number of constants which have to be determined experimentally for each instrument; these constants apparently depending not only on the instrument, and the person using it, but also to some extent

upon the nature of the lights to be compared. The most hopeful of all the instruments described for colour photometry seems to be the mixture photometer of Grosse. In this instrument the lights A and B, to be compared, are estimated not by directly measuring the ratio A : B, but by comparing two mixtures, A + *m* B and *n* A + B, where *m* and *n* are constants fixed for each instrument. Here the colour difficulty is got over by mixing the lights, and the relative illuminations of the surfaces compared is varied, partly by adjusting the distances of the lights, and partly by turning the eye-piece of the instrument, the working of which depends on the phenomena of polarisation. As far as one can judge from the description, this photometer appears to be an excellent one.

The third chapter, on photometric standards, is a full and trustworthy account of the efforts which have been made at different times towards obtaining a good standard of light. Its usefulness is increased by plentiful references to original papers, as is the case with the other portions of the book. The French work was published too soon to include the final results of the work of the English Committee on Light Standards, but almost all previous work is alluded to. A short, but good, chapter on the equipment of photometric laboratories is succeeded by one entitled "electric lights," which contains a large amount of photometric matter relating to electric lighting, that has not hitherto appeared in book form.

The sixth and last chapter of the book is reserved for the distribution and measurement of illumination. As illumination is the whole object of artificial lighting, it seems strange that the consideration of it should have been so much neglected. For every photometer that has been designed for the measurement of illumination, there are at least twenty for the measurement of candle-power. The present book is, we believe, the first to take up this subject as an important part of photometry; and the ordinary reader, who has not followed the subject in the technical press, will find here much which is quite new to him. It is a subject of increasing importance, and since the issue of the French edition of this book some valuable work on it has been done by Trotter and Blondel, which should be incorporated when a new edition is called for. It is somewhat remarkable that no allusion is made to the diffused system of lighting by inverted arc lamps, or corresponding arrangements of glow lamps, in which the lights themselves are hidden from view, the rays being directed to walls and ceilings for subsequent diffusion downwards. This system has been used on the continent and in this country, especially for the lighting of factories, and its use is extending. It is in reality one of the most efficient systems of lighting, although any one seeing it for the first time is apt to think it weaker than it really is. A description of it should certainly find a place in a book such as this. There is, however, a large amount of new matter given in this chapter, and the only fault to find is a minor one, and one for which the author is not directly responsible. In quoting the different writers on this subject, a number of terms have been introduced which are needless, confusing, and badly chosen. Such terms as "volume of illumination" and "surface of illumination" are quite needless, while the phrase "useful effect of illumination" is a very bad and misleading name for a quantity which is of doubtful importance. It follows from the definition that the "useful effect of illumination" is always greater than the illumination itself, and that it increases rapidly as the distance from the light is increased, until at an infinite distance from the light the "useful effect" of its illumination is infinite. "This result was easy to foresee," writes the author, who asserts that the criticisms to which it has been subjected "are not well founded"; and calculations are then made by means of which "the volume of useful effect," the "surface of useful effect," and the "mean useful effect" may be obtained by any one anxious to know.

In spite of a few minor blemishes, the book is a thoroughly good one. It is well printed, well illustrated, and contains a mass of valuable matter which is not to be found elsewhere. Some useful appendices by the translators conclude the work.

W. E. S.

THE NOTES OF BIRDS.

The Evolution of Bird-song. By Charles A. Witchell. Pp. x + 348. (London: A. and C. Black, 1896.)

THIS little work will be heartily welcomed by all ornithologists as the first elaborate attempt to deal in a scientific spirit with the very difficult subject of the utterances of birds. Considering the great amount of careful observation necessary to the formation of any theory on the subject, and the difficulty of recording such observation correctly and intelligibly, Mr. Witchell is to be warmly congratulated on his book. It is, in fact, a very welcome and agreeable call-note, addressed to h brethren of the craft, and urging them to come and test the flavour of the food its author has discovered. Should any of them be critical of details, as indeed in such a subject they inevitably must be, it is to be hoped that the call-note will not change into an "alarm"; for however much we may differ from Mr. Witchell in detail, we shall hardly be disposed to quarrel with the main line of his argument, and we shall be grateful to him for his work as a pioneer. Personally I am glad to acknowledge that during the present season of song I have derived the greatest benefit from this book, which fortunately appeared at the very time when fresh observation was most easy and agreeable.

Starting with Darwin's theory of the origin of voice, Mr. Witchell states his belief that it was first occasioned by fear or anger in combat, and that, consequently, the earliest cries were alarm-cries. He then proceeds to show that "the first call-notes of birds were probably mere adaptations of alarm-cries, the use of which was induced by the influence of mutual aid among associated individuals." Rapid reiteration of call-notes had a tendency to produce something in the nature of song; and Mr. Witchell is able to produce several good examples of this in species which are still incapable of any true vocal effort, though he gives one or two, *e.g.* the willow-warbler, about which I feel, as yet, uncertain. Closer observation on this point is much wanted, but I can quote one case, that of the tree-sparrow (not mentioned by Mr. Witchell), which may occasionally be heard in the spring constructing a quasi-song by linking call-notes together. Mr. Witchell is careful not to commit himself to the view

that *all* songs were so developed; but it is quite possible that this view may eventually hold the field, if due credit be given to the inventive and imitative powers of the bird, which, having once found a voice, would naturally make constant use of it and thus develop its resources. As regards imitation, he has much to say later on; but throughout the book he seems to me to neglect what I should call *invention*, or the varying use of the voice for the mere pleasure of using it. I am pretty confident that many birds will go on uttering "call-notes," and even songs, not for any special immediate purpose, but to express a certain sense of comfort, and for the pleasure derived from the effort. A good example of this is the greenfinch, a bird in the interpretation of whose notes Mr. Witchell surprises me; but want of space forbids me to enter into details.

Next follows a chapter on certain noticeable incidents of bird-song, which may be strongly recommended to those who are beginning to make observations of the utterances of birds. They will find their attention directed to such points as this: that variation from the specific type of song is generally to be heard at the end of the phrase, and, conversely, that the first part of the phrases sung by allied birds have the most resemblance to common types. Or, again, that the call-notes and alarms of allied birds are more alike than are their songs—a point of great importance. A theory (p. 70) to account for the fact that the most voiceful birds are, as a rule, small, is also worth consideration.

But it is in the last three chapters that we find the most original and interesting contributions to the subject. Of these, chapters vii. and ix. are on the influence respectively of heredity and imitation, and between them the author has placed a shorter one on variation. The chapter on heredity, though it would be the better for a thorough revision, both in the ordering and expression of the matter, is nevertheless of great importance. Here Mr. Witchell endeavours with success to trace the influence of the principle of heredity by comparing the notes and songs of allied species, so as to provide fresh scientific reasons for their connection in classification. As might be expected, he finds more to the purpose in call-notes and alarms than in songs, and more in the first phrases of song than in the conclusions. Some things in this chapter may astonish us, such as the statement that the buntings are more closely allied by voice to the pipits than to the finches (p. 121), and the whole of a paragraph on p. 113, in which the songs of nightingale, lesser whitethroat, and cirl-bunting are declared to resemble each other; but the general value of this part of the work is beyond question, and cannot fail to act as a fresh stimulus to many field ornithologists.

In chapter ix. Mr. Witchell discusses his second leading principle in the development of song, viz. imitation, whether of the voices of other birds, or of prevalent sounds in fields and woods. This is, I think, his favourite topic, and the one which he has most carefully elaborated by observations and records. He has gone far beyond any previous writer in the wide range of result he ascribes to this influence, and his conclusions as to the imitative capacity of many species will have to be most carefully tested. For the last two months I have been endeavouring to test them with varying result. As regards the thrush and the robin, he has already convinced me that they mimic much more than I had suspected, though I cannot detect in these songs more than an occasional imitation of which I can be *quite certain*. In others, such as those of nightingale, redstart, whitethroat, &c., I can as yet hardly detect any at all, though I have been listening to these voices constantly and carefully for more than twenty years. As far as my own experience goes, I should be disposed to think that Mr. Witchell often exaggerates superficial and accidental resemblances; but on the other hand, I can readily grant that his ear may be more accurately trained than mine for the purpose of detecting them. And in any case I must refrain from detailed criticism, which can be but the pitting of one man's experience against that of another.

The short chapter on variation might well be amplified. Not only do many birds show dialectic variation in different localities, but in the same locality the singers vary from each other, and even the individuals constantly vary from one minute to another, as I have often observed this spring. And yet the specific type is always preserved, which is owing in great degree to the peculiar tone or *timbre* of the vocal instrument of the species—a point to which I hope Mr. Witchell will turn his attention more closely than he seems yet to have done.

It gives me pleasure to sign a notice in which I hope I have done justice to the merits of this work, for in a book published a year and a half ago, I alluded to Mr. Witchell's theory, as it was then known from papers in the *Zoologist*, with somewhat scant respect. Some fanciful conclusions to which he formerly gave prominence, have in this volume retired modestly into the background.

W. WARDE FOWLER.

THE STRUCTURE OF MAN.

The Structure of Man: an Index to his Past History. By Prof. R. Wiedersheim, translated by H. and M. Bernard. 8vo, pp. xxi + 227. (London: Macmillan and Co., 1895.)

THIS book, which is a translation of Prof. Wiedersheim's "Der Bau der Menschen," by H. and M. Bernard, has the advantage of a preface and notes by Prof. G. B. Howes. As the preface states, the object of the work "is an endeavour to set forth the more salient features in the anatomy of man which link him with lower forms, and others in that of lower forms which shed special light on parts of the human organism." Such books as this give to the scientific study of anatomy much assistance by calling attention to the interesting deductions which may be made by a careful study of the different variations met with in the dissection of man and animals. In order that such deductions may be placed on a firm basis, it is necessary to have careful observations recorded in a very large number of cases, and in the English preface of Prof. Wiedersheim's book a special tribute is paid to the work carried out in the different anatomical schools through the "Collective Investigation Committee of Great Britain and Ireland." The English translation has in a great many places been added to, and brought up to date in notes by Prof. Howes. Some of these additions are exceedingly valuable in themselves, and further, their

practical use is increased by the fact that they give references to the most recent literature on the subjects with which they deal. The plan of the book has been well thought out, and its arrangement is such as to render the search for information contained in it an easy one. Special chapters are set apart for the integument and tegumental organs, the skeleton, the muscular system, the nervous system, the sense organs, the alimentary canal and its appendages, the circulatory system, and the urinogenital system. The arrangement of the matter in each of these chapters is further carefully classified. In certain places the terms used lack the accuracy which is essential to a work on human anatomy, thus (p. 91) on the "comparison of the fore- and hind-limbs of man," to speak of the leg and arm of the adult as "opposite extremities" is vague and inaccurate. Again, in the description of the lower end of the humerus (p. 77) confusion is caused by the application of the term "ent-epicondylar" foramen to the occasional perforation of the olecranon fossa, instead of confining this name for the foramen partially enclosed by the ent-epicondylar process, which is sometimes present in man. The theories put forward in some parts of the book to account for facts observed in man, seem scarcely adequate; thus, for instance, on p. 38 we are told "the shifting of the centre of gravity towards the dorsal side explains why the vertebral ends of the lowest ribs are so firmly attached." Yet a very similar condition of the more posterior ribs obtains in quadrupeds, in which animals a shifting of the centre of gravity towards the spine does not occur. In another place (p. 55) it is stated that in lower races, as in the apes, the process of obliteration of the cranial sutures beginning in the frontal region and proceeding backwards "naturally causes an earlier limitation in the growth of the anterior lobes of the brain; whereas in the higher (white) races, when the fronto-parietal suture disappears only after the obliteration of the parieto-occipital one, these lobes are capable of further development." The obliteration of the sutures in the frontal region does not necessarily limit increase in growth of the frontal bones, much less that of the contained brain, and further, it has been shown that the frontal lobes do not in their growth vary with the changes in position of the fronto-parietal suture. The posterior boundary of the frontal lobe—fissure of Rolando—has a relatively constant position during brain growth, so that a relative increase in size of the frontal lobes, in white races, does not take place during the time that certain of the cranial sutures are closing, or even after birth. In the chapter on the nervous system, it is a pity that the old and superseded observations of Möller are retained, and we read, "Man differs from the Anthropoids in the preponderance of the frontal lobe and, to a lesser degree, of the occipital lobe, and in a corresponding backward extension of the temporal lobe. The parietal lobe is about equally developed in the brains of man and Anthropoids" (p. 131). As a matter of fact the great extent of the parietal lobe, together with a corresponding decrease of the occipital lobe, is a human characteristic. In the Anthropoids the upper part of the posterior boundary of the frontal lobe is relatively further back than in man. It is a curious fact that Prof. Wiedersheim's book should adhere to the old view, that a well-marked occipital lobe is a human characteristic, since it has been definitely shown that this part of the brain, which was at one time denied to apes, really attains in them its greatest relative development, and further, it is in the lower apes that a maximum is reached.

The presence of numerous illustrations, and of a glossary of the zoological terms used, in spite of its many failings, is sure to render this interesting and easily read translation of Prof. Wiedersheim's book very popular.

OUR BOOK SHELF.

The Official Guide to the Norwich Castle Museum. By Thomas Southwell, F.Z.S. Pp. 294. (London: Jarrold and Sons, 1896.)

"THE value of a museum will be tested not only by its contents, but by the treatment of those contents as a means of the advancement of knowledge." This remark of Sir William Flower's is the key-note of the Committee of the Norwich Castle Museum, and in consonance with it the admirable guide-book at present before us has been constructed. The book is an interesting and useful guide to the collections in the Museum; it is not merely a catalogue, but a popular natural history in which the specimens in the cases are used as illustrations. Assisted by this guide, sightseers will pleasantly acquire a knowledge of the leading characteristics of the different groups of animals, and students will gain a large amount of sound instruction.

The scientific value of the book lies in Mr. Southwell's orderly review of the natural history specimens in the Museum. This forms the greater part of the contents; but there is also an historical account, by the Rev. Wm. Hudson, and a description of the collection of pictures, by Mr. G. C. Eaton.

The Museum was founded in 1825, and it existed as a private institution until 1894, when it was taken over by the Corporation, and established in Norwich Castle. The scheme for the conversion of the Castle, which had been condemned as a prison by the Prison Commissioners, into a museum and recreation grounds, was due to Mr. John Gurney, who died in February 1887. Mr. Gurney gave £5000 towards the scheme, which nucleus was afterwards increased by subscription to £14,389. The new home of the Museum collections was opened two years ago, and it is a credit to the Norwich Corporation and people. Very few local museums are better arranged than the one at Norwich, and in none is the educational object of the institution kept more in mind. To say that Mr. Southwell's guide is worthy of the Museum is, therefore, equivalent to stating that it possesses all the features which will make its readers appreciate to the fullest extent the *utile et dulce* of the collections.

Latitude and Longitude: How to Find them. By W. J. Millar. (London: Charles Griffin and Co., 1896.)

IN this concise little book the art of navigation is treated from an elementary standpoint. Commencing by explaining the meaning of a few mathematical expressions, including triangles, the author goes on to trigonometrical ratios and logarithms, and shows how they are brought into use for the purpose of finding a ship's position. The errors that have to be corrected are explained, as well as the determination of time and the use of the sextant.

The theory of the every-day work at sea, and also of lunar distances and Sumner's method, is given, so that with a small amount of mathematical knowledge a student of navigation can master the chief problems required to find the latitude and longitude at sea.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I HOPE that my friend Prof. Lankester will forgive me if I find myself unable to accept the version which he has published of a portion of the remarks which I made at the recent discussion at the Linnean Society.

I entirely agree with Mr. Mivart, that the "Problem of Utility" really involves the validity of the Darwinian theory.

I stated in my remarks what I have often stated before, that I was more and more confirmed in the belief that specific characters in flowering plants are utilitarian. I showed that this was obviously so in familiar cases. If time had allowed, I might have strengthened my position by reference to the large amount of important and convincing work which has been done in this direction in other countries. At home, for reasons which are not far to seek, this kind of research is now almost entirely neglected. The result is that the Darwinian theory of organic evolution seems hardly to have a convinced supporter left except Mr. Wallace. In its place we have the "Physiological Selection" of Dr. Romanes, the "Discontinuous Variation" of Mr. Bateson, and, last of all, the extended "Correlation Principle" of Prof. Lankester. A common feature of each is their more or less definite rejection of the principle of utility as accounting for specific characters.

I was examining with Mr. Darwin, at Kew, a collection of Pitcher-plants (*Nepenthes*). The specific differences lie mainly in the appendages of the pitchers. I hazarded the remark that it seemed hopeless to attempt to explain these on teleological grounds, and that it was difficult to believe that the differences were not due to merely fortuitous variation. Mr. Darwin replied, that he was not prepared to admit it. He gave two reasons: (1) that many plant-structures which at first sight it was scarcely conceivable could be adaptive, had been proved to be so in the most unexpected manner; (2) that to assume that phenomena were not susceptible of explanation, was to shut the door to discovery.

Now I stated, perhaps unnecessarily, that the two reasons were not on the same plane. The first implicitly asserts an inductive principle, the probability of which, it seems to me, subsequent research confirms every day; the second, I described as of a moral kind. It would have been better to have spoken of it as *ethical*, or as a counsel of scientific prudence. In point of fact, I never used the word "immorality": that was imported into the discussion, and I think in a somewhat sarcastic spirit, by Prof. Lankester himself.

A more serious point, however, is this. Prof. Lankester quotes me as the authority for the statement that Mr. Darwin "appears to have deprecated . . . the invocation of this theory of correlation as an explanation of cases of apparently useless parts in animals and plants." Now I made no reference whatever to correlation, which I do not think enters into the particular case I referred to. The question I put to Mr. Darwin amounted simply to this:—"Is it probable that these specific differences will turn out to be adaptive?" And his reply was, in effect: "I think it is."

I confess that the use to which Prof. Lankester has turned the correlation principle fills me with some surprise. As with every difficulty which is from time to time brought up against the Darwinian theory, it will be found that Mr. Darwin has thoroughly considered the matter himself, and has said pretty much all that is to be said about it. The whole subject is exhaustively discussed in the twenty-fifth chapter of "Animals and Plants under Domestication." He treats at considerable length "the cases in which we can partly understand the bond of connection," and then gives more briefly "the cases in which we cannot even conjecture, or can only very obscurely see, what is the nature of the bond." This is characteristic of Mr. Darwin's fairness; he adopted precisely the same method in regard to cases which seemed to make for Lamarckism, and were not readily explicable by the principle of natural selection. Most of these have been since cleared up, and I do not doubt that the same thing will happen in regard to correlation. The *nexus*, which is now obscure, will sooner or later be revealed.

The animal organism is a "complex" which, in the vast majority of cases, we are far from understanding. It has undergone in a high degree what Mr. Herbert Spencer calls "integration." It is not surprising, therefore, that organic correlation has been obscured. Prof. Lankester lays it down, that "presumably also plants" are in the same predicament. But I do not admit this. In plants integration has not been carried to anything like the same extent. For many purposes of biological research I therefore hold with Mr. Darwin, that plants are better subjects of investigation than animals, because the phenomena are less complex.

The result is that in plants most cases of correlated variation are at once explicable. All the appendicular organs are homologous. A variation which affects one runs through the whole. Amongst many thousand Snowdrops from Asia Minor, grown at Kew this spring, a few had exceptionally broad leaves; this was accompanied by a corresponding dilatation of the perianth-segments. There is a variety of the common oak with marbled foliage. A tree at Tortworth has borne acorns, and these are striped. At first sight it might seem odd that a variation in foliage and fruit should be correlated. But it is not so: the marbling is due to the partial suppression of chlorophyll in those portions of the ground-tissue which are exposed to light; and this tract of tissue is continuous in the leaves and the carpels.

I cannot but think that even in animals, of which I know little, Prof. Lankester is building on a rash foundation in attempting to generalise widely from cases in which, in the light of present knowledge, the obvious but, as he thinks, useless distinctive character may (or may not) be linked with the unobvious adaptive variation.

It seems to me that when an explicable correlation persists in a species, we are not justified in assuming any part of the chain to be useless. The whole is, in fact, part of the specific character; and this was what I took to be Prof. Weldon's point. I do not see that our ignorance of the nature of the "bond" makes any difference; nor do I see how Prof. Lankester extricates himself from the effect of his admission that the parts of the chain are always subject to selection. It seems to me that we are justified in inferring that what survive as specific differences do so because they are useful.

I doubt if the case which has so impressed him is a very satisfactory one. He thinks that in "tropical regions" the colour of the skin is linked with the chemical activity of the leucocytes in the blood. Assuming that immunity from fever is due to the latter, he infers that the former is not a "useful character." This is, in the present state of our knowledge, taking a good deal for granted. But I frankly admit that such a case, if completely established, would give the utility of specific characters, and with it the Darwinian theory, a serious blow; and Prof. Lankester would have the satisfaction of arriving at the same result as Dr. Romanes, but by a different path.

But is he sure of his ground? Mr. Darwin touches on the connection between "complexion and constitution," but does not appear to think the evidence points to any definite conclusion. Nor, I confess, do I, from such facts as are within my knowledge. I have sent a good many men from Kew to Africa, and the belief of my staff is that fair men enjoy better health than dark. But I do not consider that the data are sufficient. On the other hand, men of African descent, transferred from the West Indies to Africa, are said to be more susceptible to febrile maladies than the natives. Certainly the natives of India do not appear to enjoy any immunity from fever. "It is," says Sir Clements Markham, "by far the most prolific cause of death, carrying off . . . very many more than all other disease and accidents put together" (except cholera). I cannot but be impressed with the fact, because it was to combat this state of things that the Government of India introduced Cinchona cultivation, by far the most important enterprise in which Kew ever took part.

It appears to me that the relation of a stationary population to local febrile diseases is governed by natural selection, and has possibly nothing to do with epidermal pigment. The more susceptible die off, the more immune survive. Variation in the phagocytes would do the whole business. In this way disease and population reach an equilibrium. In some cases a disease actually attenuates, to recover its virulence when, as in the case of measles in Fiji, it reaches new ground. At any rate, I think Wells's theory can hardly be accepted as a scientific fact. But it does not follow that epidermal pigment is useless because one explanation of it seems to fail.

I must add a few words about specific differences. Some one has recently observed that Mr. Darwin has given no definition of a species. I do not propose to attempt the task. But the majority of botanists demand that a "good species" shall be distinctly marked off from every other by definite and tangible characters. The members of the group may either conform pretty closely to a common type, or exhibit a good deal of variation amongst themselves, and this variation may be sometimes indifferent, sometimes adaptive. Such a variable group is generally considered to contain species "on the make"; but the indifferent variation will be remorselessly, if slowly, brought to book by natural selection. A botanical species is then a discontinuous group marked off by characters which I believe to be adaptive.

I have a strong suspicion that zoologists have a different conception of a species from that of botanists. I once heard Prof. Huxley say roundly, at a meeting of the Linnean Society, that there were no such things as species at all. The subject under discussion was a group of *Salmonidæ*, and he said that if the forms were arranged in a row, it was a purely arbitrary matter how any one chose to cut it up into species. But the same state of things might be paralleled amongst plants—as, for example, in *Hieracium*. The occurrence of such cases is not incompatible with the fact that the majority of species probably admit of being sharply defined, and are, in other words, discontinuous. This is, at any rate, the case with plants, and I do not see why it should not be equally so with animals. If, however, zoologists cut their species finer, it is intelligible that they may find difficulty in recognising the distinctive characters as adaptive. Prof. Poulton, in the discussion at the Linnean Society, went the length of saying that he saw no objection to giving a name to every distinct form, leaving it to be afterwards decided if it were or were not entitled to specific rank. Such a proceeding, if general, would throw taxonomy into a state of chaos. It has been adopted by a few botanists; but by common consent their writings, though not without a certain interest as studies in variation, have been excluded from serious taxonomic literature.

W. T. THISELTON-DYER.

Kew, July 20.

IN his letter, published in NATURE of July 16, Prof. Lankester has formulated with great clearness his views concerning the utility of specific characters; and he explains that his chief object in doing so is to draw attention to certain statements of mine, which he declares to involve a serious logical fallacy. While I am grateful for the courtesy with which Prof. Lankester has tempered his condemnation of my logic, I am still unconvinced; and the point at issue is so important that I am anxious to state, as clearly as I can, what my own position is. I may perhaps conveniently begin by quoting in full a passage from a former paper. Last year I wrote as follows:

"In order to estimate the effect of small variations upon the chance of survival, in a given species, it is necessary to measure *first*, the percentage of young animals exhibiting this variation; *secondly*, the percentage of adults in which it is present. If the percentage of adults exhibiting the variation is less than the percentage of young, then a certain percentage of young animals has either lost the character during growth, or has been destroyed. The law of growth having been ascertained, the rate of destruction may be measured; and in this way an estimate of the advantage or disadvantage of a variation may be obtained" (*Roy. Soc. Proc.*, vol. lvii. p. 381).

Prof. Lankester objects to this passage; and, if I understand him rightly, his objection may be stated in this way:—Admitting it to be proved that variation in a certain dimension, among young animals of a species, is associated with change in the death-rate, so that when this dimension increases the death-rate increases, and when it diminishes the death-rate diminishes; so that by ascertaining the magnitude of this dimension in a young animal you can accurately measure its chance of becoming adult; —admitting this relation to hold through a range of experience sufficient to form the basis of a reasonable induction, you have still no right to say that change in the observed dimension is a cause of the subsequent change in death-rate: for the two observed phenomena, namely the change in the observed dimension and the subsequent change in the death-rate, may alike be due to variation in some unobserved character, which alone is effective in causing change of death-rate.

In other words, you have a phenomenon, namely death-rate, preceded invariably by two or more phenomena of structure or function; and these are so associated, that from a known change in the antecedent group of phenomena, affecting always every member of the group, you can infer a change of known magnitude in the death-rate. Under these circumstances, Prof. Lankester thinks it legitimate to pick out one of these antecedent phenomena, and to speak of it as the only effective cause of change in death-rate, the other changes, although equally universal, being merely unimportant concomitants of this one essential change. He further finds something extraordinary in my logical position when I disagree with him, and considers every member of the group of correlated changes which invariably precedes change in death-rate as one of the causes of that change.

I have ventured to restate Prof. Lankester's position in my own words, in order to show what I believe him to mean. If I have in any way misrepresented him, I trust he will forgive me.

My own view seems to me identical with that held by a large number of persons, from Hume onwards; and for that reason I hope Prof. Lankester will not think I am indulging in an "empty wrangle" if I ask whether he accepts the following statement:

"We may define a cause to be *an object, followed by another, and where all the objects, similar to the first, are followed by objects similar to the second*, or in other words, where, *if the first object had not been, the second never had existed*. . . . We may . . . suitably to experience, form another definition of cause, and call it, *an object, followed by another, and whose appearance always conveys the thought to that other*. But though both these definitions be drawn from circumstances foreign to the cause, we cannot remedy this inconvenience, nor attain any more perfect definition, which may point out that circumstance in the cause, which gives it a connection with the effect. We have no idea of this connection; nor even any distinct notion of what it is we desire to know, when we endeavour at a conception of it" (Hume: "Inquiry concerning Human Understanding," § vii.).

When I have spoken of cause and effect, I have always endeavoured to use the words in accordance with the definition given in this passage or in Kant's extension of it; but Prof. Lankester seems to go beyond it. At least, the process of selecting one out of a group of universal antecedents, and calling that one alone the effective cause of the consequent, seems to me to involve precisely that knowledge which Hume and all his followers disclaim. For unless he knows "that circumstance in the cause which gives it a connection with the effect," how does Prof. Lankester pick out that one of the universal antecedents of an event which he chooses to call the cause? Such selection would have been impossible to Hume; and if Mill had regarded it as possible, he would hardly have defined a cause as "the sum total of the conditions, positive and negative taken together; the whole of the contingencies of every description, which being realised, the consequent immediately follows."

It is the assumption of the right to choose one out of a number of universal antecedents, and to regard this as the only cause of the consequent, which I have ventured to call illogical: and since Prof. Lankester has quoted Mill against me, I would ask him to read Mill's opinion of such a proceeding.

The prevalence of this practice in biological speculation tends more than any other habit to that neglect of the real complexity of the phenomena of life which Prof. Lankester himself so justly deprecates. For example, the contraction of the body of an amœba has been discussed of late years in two ways. Observers, following Prof. Lankester's method, have discussed the question, how much of the body of an amœba is the effective cause of its contractility? It is possible roughly to divide the body of an amœba (neglecting the nucleus) into an apparently more solid net-work or sponge-work, and an apparently more fluid substance in the meshes of this sponge-work. The question has been hotly debated, which of these two substances should be regarded as the essentially contractile element, the other being an unimportant concomitant. Each alternative has had its advocates, and neither party has convinced the other. Readers of NATURE are aware that a short time ago Prof. Bütschli attacked this question from the standpoint which I am here advocating: that is to say, he regarded each of the substances, invariably antecedent to contraction, as one of the causes of the contraction. By considering the changes in the relation between the two, Prof. Bütschli was at least enabled to make a dead

model which imitates with remarkable exactness the phenomena of amœboid movement; while the suggestion that such movement falls into the same category as the change in surface-tension at the boundary between two not-living liquids with change in the constitution of either, is a most important step in the "explanation" of contractility in general.

Here then is a phenomenon which had for years been rendered more obscure by the attempt to fix upon one of its two universal antecedents as its effective "cause"; while some kind of explanation was at once forthcoming when both antecedents were taken into account. It would be easy to multiply examples of this kind; but perhaps the foregoing may suffice.

I would only now reiterate my hope that in trying to make plain my own position I have not in any way misrepresented that adopted by Prof. Lankester. W. F. R. WELDON.

Marine Biological Laboratory, Plymouth, July 18.

IT appears to me that Prof. Weldon's argument, referred to in NATURE of July 16 (p. 245), is accurately represented in the following illustration. It might be an established fact, although it is not in reality, that there was a constant correlation between baldness and short-sightedness. Suppose that it were so, and that in a country where conscription was enforced, short-sighted men were exempt from military service: that is to say, let us suppose that a test was applied to the eyes of all men at a certain age, and that those whose vision was not normal were rejected and allowed to return to the peaceful pursuits of civilian life. These rejected men would, on the hypothesis, be all more or less bald, and according to Prof. Weldon's position, it would be quite as correct to say that they were not in the army because they were bald, as to say they were rejected on account of myopia. Now it is quite true that the officers of the army medical staff might save themselves trouble by rejecting all bald-headed men, because, on the hypothesis, all such men would be short-sighted; but it would be obviously wrong to conclude that a good development of hair was essential to military efficiency.

Prof. Weldon argues that it is enough to prove that individuals of a species are selected according to a certain character, and that it is unnecessary to discover whether survival depends directly on this character, or on some other with which it is correlated. He seems to have concentrated his attention on the attempt to demonstrate directly the occurrence in nature of individual selection, in this peculiar sense, and to be temporarily indifferent to all other questions.

Prof. Lankester suggests that specific characters would be explained if it were proved that they were correlated with adaptive characters. It is of course perfectly true that if there were such constant correlations, then the survival of adaptive variations would involve also the survival of the indifferent characters connected with them. But the difficulty is to prove that in many cases there are *any* important differences of adaptation between allied species. It is easy enough to define the specific differences and specific characters; but to find any differences which correspond to differences in the mode of life, is often exceedingly difficult. It is true we find in most cases some differences in the conditions of life of closely allied species, but we do not usually find peculiarities of structure which can be said to be adapted to those differences. Who, for instance, can say what adaptation is present in the pilchard or sprat differentiating either from the other or from the herring? The question, therefore, is not whether indifferent specific characters are correlated with useful characters, but whether species of a single genus are distinguished from one another by any characters which can be proved to be useful or adaptive. The tongue and hyoid of the woodpeckers are beautiful adaptations; but are there any differences of selection value between one species of woodpecker and another? The denial of the utility of specific characters means, not merely that some specific characters are indifferent while others are adaptive, but that adaptations are not in the great majority of cases distinctive of species at all. Therefore, as the late Mr. Romanes often ably demonstrated, natural selection is not a theory of the origin of species, but only a theory of the origin of adaptations. The further objection, that a theory of selection is only of secondary importance in comparison with a theory of the origin of variations, I will not enter upon on this occasion. J. T. CUNNINGHAM.

College of Surgeons, July 17.

The Position of Science at Oxford.

WILL you allow me a few lines in which to express my entire agreement with your recent article on this subject, if only to emphasise the fact that I am not the author of the article, and that the opinions there expressed are not those of an isolated individual. The reason for the comparative neglect of natural science at Oxford is that, however well-disposed some individuals may be, the college tutors and lecturers as a rule dislike it. They dislike it for two reasons. First, because it cannot be taught in the college parlours called lecture-rooms; and second, because they are, as a rule, ignorant—owing to their own defective education—of the nature and scope of the immense field of study comprised under the head "natural science." They do not know either the enormous educational value of natural science, or its vital importance to our national life and development.

And lastly, if they did know, there is no conceivable motive which could operate so as to induce them to sacrifice some of the rewards and educational domination, which are at present enjoyed by the long-established classical and historical studies, to newer lines of work in which the present beneficiaries and their academic offspring can have no share.

The situation is a "dead-lock," and only an intelligent Parliamentary Commission (if such is possible) can put matters on to a fair and healthy basis Probably the scandal of the present paralysis of our beloved Oxford will have to become even greater and more outrageous than it is at this moment, before the necessary remedy is applied.

But happily the vitality of Oxford is indestructible. The misused and monopolised resources of Oxford will assuredly some day be devoted to the true purposes of a great University.

E. RAY LANKESTER, Linacre Professor, Oxford.

THERE are some points in the article on this subject in NATURE of July 9, which call for comment. The defects pointed out are not, I believe, due to the causes mentioned by your correspondent. The fault lies mainly in the public schools. The lower forms of public schools are, as a rule, mainly classical, the division into sides, classical, modern and science, only beginning when a boy has finished about half his school career. The choice of sides is chiefly left by the parents to the masters, and since in the lower forms these masters have, as a rule, little sympathy with any kind of work which is not purely classical, boys of ability are drafted as a matter of course into the classical side. The boys who enter the science side are often the failures of the classical side, and unless special care is taken by the science masters, even they are kept at classics until it is hopeless to make them into respectable science scholars. Naturally there are many exceptions; some clever boys have enlightened parents, and others, early developing a taste for scientific matters, persuade their parents to allow them to give up the dead languages. There are also some classical men who admit that other subjects than their own have educational value. But the rule is for the able boy to be kept at classics, while his less favoured brother is sent to science. I know that this is the case at the five public schools with whose working I am familiar, and I have little doubt that the science masters of other public schools have the same experience. Occasionally able boys are recruited from the modern side, and it is these boys who are practically shut out from Oxford. However small the knowledge of Greek required for passing responsions may seem to a classical man, it is no light matter for a boy who has it all to learn in little more than a year, and who has much other work to do during the time. At Cambridge the necessary knowledge of Greek is almost nominal, and it is a pity it is not abolished altogether. If both Universities would substitute a good knowledge of German—so necessary for every scientific student—for the very imperfect and quite useless modicum of Greek which they now require, it would result in a great saving of time to many science students, and ultimately in raising the science standard at both Universities.

H. B. BAKER.

IN your article on "Science at Oxford," in NATURE for July 9, you say: "It may be objected that every public school has one or more science masters of tried capacity, and that science is a compulsory subject in nearly all."

The first part of this statement may be correct, but I venture to demur to the second. Certainly at one school I could name,

where over £10,000 has been spent on scientific equipment, science is not a compulsory subject; and, in fact, it is practically impossible to get science teaching on the classical side.

It would be interesting to know how far science is compulsory in the various public schools. I have no doubt there are others, but I only know of two—Eton and Clifton—where it is.

"A Parent."

Discharge of an Electrified Body by Means of the Tesla Spark.

It has been shown that a body charged with electricity may be discharged by means of the rays from a Röntgen bulb. I find, also, that an electrified body is rapidly discharged by the influence of a high-frequency spark, such as that produced by the Tesla apparatus. The discharging action was shown in this way. A high-frequency spark was produced between two rather blunt points, one inch apart in air, no bulb being used. A gold-leaf electroscope, placed far away from the influence of the spark, was used to test the electrical condition of the charged bodies—viz. a stick of sealing-wax and a rod of glass. The sealing-wax was rubbed, and the electroscope indicated that it was well charged. It was again rubbed, and then brought to within a foot of the points, and by means of a key in the battery circuit the Tesla coil was thrown into action for an instant. On testing the sealing-wax rod with the electroscope, it was found to be entirely discharged. A similar experiment was next made with a glass rod; the glass rod was entirely discharged by the Tesla spark. From a previous experiment, it was seen that the electrification of the rods was dissimilar. The influence, then, of the high-frequency spark is to discharge electricity of either sign.

Oxford, July 17.

On the Occurrence of the Pelagic Ova of the Anchovy off Lytham.

Hitherto no free eggs of this species have been procured in Britain, though Mr. Jackson found ripe females off Southport in June 1878. Day observes, in the "Brit. Fishes," that the anchovy spawn off our coasts in September and December; though in June specimens have been found with enlarged ova, and so tender that they burst on the slightest interference. On June 26 last, however, Mr. R. L. Ascroft, of Lytham, obtained certain ova in the tow-nets used off Lytham Pier, which he courteously sent for examination in a solution of formalin. These eggs agree in all respects with the descriptions and figures of Hoffman, Wenckebach, and Raffaele, though somewhat larger.

Prof. Hoffman found that the anchovies of the Zuyder Zee were ripe in the months of June and July, and that the eggs were of an oval form, and about 1 mm. in length. In July 1886, Wenckebach captured the same eggs in his tow-nets, and hatched them on the third day. The egg is ovoid, and the yolk reticulated as in other clupeoids, such as the sprat. Raffaele procured the same egg at Naples—from May to September—and also ascertained that hatching took place after two or three days. He gives the long diameter of the egg as 1·15 to 1·25 mm., and the shorter at 0·5 to 0·55 mm. The larva is provided with a reticulated yolk of little depth, but of great length, extending, indeed, considerably beyond the middle of the body, while the notochord is unicolumnar. In two or three days after hatching the yolk had greatly diminished, the pre-anal fin-membrane was augmented, and the dorsal had likewise passed much further forward. The buccal aperture had also opened, and four branchial arches were visible. The yolk had completely disappeared about the fourth or the fifth day, and pigment occurred in the eye and along the dorsum. The post-pyloric portion of the gut was transversely ridged.

The eggs sent by Mr. Ascroft were, for the most part, advanced; the embryo occupying the long axis of the egg, as usual in such cases, and as shown by Raffaele. The long diameter ranged from 1·295 to 1·447 mm., the shorter diameter being almost constant at 0·685 mm.; they are thus larger than those from the Mediterranean and the Zuyder Zee.

Interesting accounts of the occurrence of anchovies off the British shores have been given by Prof. Ewart and Mr. Cunningham, and they would seem to be by no means so rare as at one time supposed. Prof. Hoffman thought that very rapid growth occurred during the first year of the life of the anchovy, so that those spawned in June and July reached a length of 12 cm. at the end of October, and Dr. Hoek appeared to agree with him. Ehrenbaum, however, asserts that the young anchovies referred to are in their second year; and this would be more in harmony with what is known of the herring, the pilchard, and the sprat. This author considered that the anchovy breeds when two years old.

Gatty Marine Laboratory, St. Andrews, July 16.

Information on Scientific Questions.

Dr. Brown Goode is quoted in Nature of July 16 (p. 252), as saying "he cannot think of any scientific subject regarding which a letter, if addressed to the scientific bureaus in Washington, would not receive a full and practical reply." I infer from this that the replies are prompted by the courtesy of the officers of the various departments, and that the public of the United States possess no right to demand them. If this is so, surely Dr. Brown Goode's scoff at British Government departments is disingenuous, to say the least of it.

But though we have no *right* to apply for information to Government departments, it must have been the experience of great numbers of people that information may be most readily obtained, and that only very exceptionally does a public officer fail to reply to any reasonable inquiry relating to his own branch of science—or art. I have myself made frequent inquiry of officers of the British Museum, both at Bloomsbury and South Kensington, and in every case (save one) have had courteous and satisfactory replies from those to whom my inquiries were addressed. I have received similar treatment from the Department of Science and Art, from the Society of Antiquaries, from the Board of Trade, from the Agricultural Department, from the Royal Academy, from the School of Mines, and from other bodies which, though in this country they are of a pseudo-private character, would in the States probably come under some public department.

It may be that the experience of others has been less favourable than mine; but this I find it difficult to believe, and unless Dr. Brown Goode means us to understand that the Washington bureaus may be peremptorily applied to for information, it would be seemly to withdraw the implied charge of discourtesy which he has levelled at our public officers.

I would further point out that in many of our country towns and cities there exist municipal museums, to which local inquiries are first addressed, whence information may be obtained, at, I confess, considerable inconvenience to the curators. I have myself had inquiries on all sorts of questions from agriculturists, medical men, colonists, genealogists, artificers, tradesmen, youthful collectors, and the general public, some of which have taken me two or three hours, and occasionally a microscopic examination of specimens, to solve, and doubtless many other persons could tell of similar experiences. It is quite remarkable how entirely the public have adopted the view that a curator of a museum is a fit and proper person to consult upon any and every subject; but my experience leads me to think that curators have brought this condition of things upon themselves.

Exeter, July 20.

James Dallas.

Horary Variation of Meteors.

Dr. Doberck, of whose paper an interesting abstract was given on June 25, informs us that shooting-stars decrease in average magnitude from evening to morning, their duration and length of path decreasing with the magnitude, while the velocity increases as the magnitude diminishes.

This larger evening magnitude is said to be "owing to the fact that the meteorites are heated to incandescence nearer the earth in the evening than in the morning," a fact deserving further explanation.

In the morning we stand on the front of the earth in her orbital motion; the earth then generally meets the meteors with the double velocity of their two motions. In the evening the meteors are overtaking the earth with a slower motion, the difference of their velocities. In the morning, therefore, the meteors enter the atmosphere with double velocity, and are burned up before nearly reaching the earth. In the evening, the slower motion enables them to penetrate further through the atmosphere before becoming incandescent.

So also most aerolites fall in the evening hours, although shooting-stars are most numerous in the morning.

The impalpable air shields the earth from those meteorites whose impact would be dangerous, burning them up by their very velocity, while giving passage to those whose slower motion renders them comparatively harmless.

London, July 18.

AUGUST KEKULÉ.

BY the death of this eminent chemist at the age of sixty-six, which took place on July 13, science loses one of her most distinguished votaries. It is only four years ago since a remarkable demonstration was held in Bonn in celebration of the twenty-fifth year of Kekulé's professorship in that University. Two years previously, in March 1890, a similar rejoicing had been held in Berlin in honour of the twenty-fifth anniversary of the promulgation of the benzene theory by its illustrious author. It appears that Kekulé was intended by his father to have been an architect, and for that purpose he was sent to Giessen to become proficient in the subject after having undergone a preliminary training of the ordinary kind at the Darmstadt Gymnasium. At Giessen he came under the powerful spell of Liebig, and having attended some lectures on chemistry by that great master, his inclination towards the adoption of this science as a profession instead of architecture appears to have received a strong impulse. After a short period of probation at the Darmstadt Polytechnicum, where he tells us he learnt chemistry under Moldenhauer, and spent his leisure in lathe-turning and modelling in plaster, he returned to Giessen and entered as a student under Liebig and Will. Even at this stage of his career he appears to have been capable of rendering material assistance to his master in the experimental work being carried on in connection with the familiar "Letters on Chemistry," in which Liebig includes the name of Kekulé among those of many other chemists now well known in science, in acknowledgment of the services rendered by the future founder of structural organic chemistry. That Liebig thought highly of his pupil may be inferred from the circumstance that he very nearly received the appointment of assistant in the Giessen laboratory, then renowned throughout Europe for the chemical work being carried on there. Instead of remaining at Giessen, however, young Kekulé went to Paris, and having sat at the feet of Regnault, Frémy and Wurtz, he was casually attracted by a course of lectures on chemical philosophy advertised by Gerhardt, who had resigned his professorship at Montpellier, and was giving private courses of instruction in the French capital. Gerhardt appears also to have recognised the capabilities of his student, and an intimate personal friendship sprang up between them. It is probable that this contact with Gerhardt acted as a stimulus in developing the particular faculty as a theoriser which must have been inherent in Kekulé, and which found expression in all his later work. From Paris, where he declined an invitation to become Gerhardt's assistant, he went for a short time to Switzerland as assistant to Von Plantu in the Castle of Reichenau. After this Swiss sojourn, and chiefly at the instigation of Bunsen, he accepted an offer from the late Dr. Stenhouse, then at St. Bartholomew's Hospital, and for a time this country had the honour of fostering young Kekulé. The bent of his mind in the direction of chemical theory is well brought out by his confession in later life that he did not derive much profit from his experience at St. Bartholomew's; but having become acquainted with Williamson, who had just completed his classical work on etherification, he appears to have found a more congenial outlet for his energies in the school of thought being evolved by that investigator and Odling, and which he declared, in 1892, to have been an excellent school "for the encouragement of independent thought." While in this country an offer was made to Kekulé that he should remain here as a technologist, but the Fatherland had greater attractions for him; his great ambition was to become attached to a German University, and he started a small laboratory in the house of a corn merchant in the main street of Heidelberg, where he received pupils. In these days of palatial laboratories, it is interesting to recall that in this little kitchen Kekulé carried out his work on the fulminates, and that Baeyer, then one of his pupils, conducted his researches on cacodyl. It is not the laboratory that makes the chemist!

Kekulé's first call as ordinary professor was to Ghent, where the Belgian Prime Minister was instrumental in getting him a modest laboratory; and here for nine years he worked with a success that can be measured by the fact that, in addition to Baeyer, he numbered among his pupils Ladenburg, Victor Meyer, Wichelhaus, and others whose names are as household words in the annals of chemical science. From Ghent he was "called" to Bonn, in which University the magnificent laboratories grew under his inspiring influence, and where he remained till the last, adding to the lustre of his reputation and shedding the light of his intellect over that country in which modern chemistry appears to have found its head-quarters.

As an experimentalist, Kekulé's contributions to science are not great as compared with the enormous influence which his genius for theorising has exerted upon the development of the science of the century. His greatest and most precious gift was his power of penetrating into the inner mysteries of molecular constitution, and it is through this work that his name will ever be revered. It was Kekulé who first gave definite form to Frankland's conception of valency, and his application of this idea to the study of the carbon compounds was nothing less than epoch-making. Out of this conception grew the famous theory of cyclic compounds, which has been prolific to an extent almost unparalleled in the history of pure science, and which from the practical side has made Germany what it is in the domain of organic chemical technology. If the life-work of any chemist of our age need be quoted as a standing protest against the *cui bono* attitude of mind which we in this country are still suffering under, and which relegates abstract theoretical studies to the realms of "academic" thought remote from human interests, let the speculations of August Kekulé be put forward as an answer crushing and complete for all time.

The present writer never had the privilege of coming into personal contact with the master-thinker who has so recently passed away. His geniality of disposition appears to have endeared him to all who came under his influence. The chemists of this country join with those of the Fatherland in mourning over the gap that has been caused in their ranks.

R. M.

NOTES.

THE International Geological Congress will hold its seventh session at St. Petersburg at the end of August next year, under the acting presidency of Dr. A. Karpinsky, and with the Grand Duke Constantine as honorary president. The session will continue about a week, and the proceedings of the Congress will not be divided into sections, as at Zürich, but will be devoted chiefly to the discussion of broad principles. Extended excursions are announced, the most important being to the Ural Mountains before, and to the Caucasus after, the meeting at St. Petersburg. Shorter excursions have also been arranged to Finland and elsewhere. Geologists who propose to attend this meeting should send notice of the excursions in which they wish to participate, before next October, to the General Secretary of the Congress. The Emperor of Russia has decided, on the favourable report of the Minister of Public Ways, to grant to all geologists duly enrolled for the meeting, free first-class railway tickets during their sojourn in Russia.

THE forty-second annual meeting of the German Geological Society will be held at Stuttgart, on August 9–12. Another important annual meeting is that of the German Anthropological Society, which takes place on August 3–6, at Spires.

THE Royal Institution of Science, Letters, and Arts of Venice offers a prize of 3000 lire for the best essay on the alluvial matter brought down from the Alps by one of the principal rivers of Venetia. The competition remains open till December 31, 1896.

AN effort is to be made to induce the Prince of Wales to place himself at the head of the movement for celebrating at Bristol, in June next year, the 400th anniversary of the discovery of North America by John and Sebastian Cabot, who sailed from Bristol. It is hoped that the foundation-stone of the memorial will be laid by the Prince of Wales simultaneously with one laid in Canada.

THE International Congress of Applied Chemistry was opened in Paris on Monday. Sixteen hundred delegates were present, of whom six hundred were from other countries. M. Berthelot, Perpetual Secretary of the Academy of Sciences, was elected President of the Congress, and delivered a powerful inaugural address, in the course of which he dwelt particularly on the relation between pure and applied science, the remarkable results obtained by the alliance of physics and chemistry, and the beneficent part that science has played in the history of the past three-quarters of a century.

THE Russian Geographical Society has awarded this year its Constantine medal to M. A. Rykacheff, for his work in the domain of physical geography. Beginning in the year 1874 with a work on the distribution of atmospheric pressure in Russia, he continued to publish a series of researches on the diurnal variations of pressure, the prevailing winds of the Caspian and the White Seas, the tides in the atmosphere, the freezing and thawing of the Russian rivers, the variations of the levels of rivers in Middle Russia, in connection with variations in the amounts of rain and snow, the diurnal variations of temperature over the tropical oceans, &c. A full list of M. A. Rykacheff's works, mostly written in German and French, is given in the yearly Report of the Society. The Count Lütke medal has been awarded to Admiral Makaroff, for his work on the temperature and density of water in the Northern Pacific, based on the measurements made in 1886–89 on board the *Vityaz*. His maps of the distribution of surface temperature in August, and of temperature at a depth of 400 metres, are especially worthy of notice. The Prjevalsky prize was awarded to M. Berezovsky, for his explorations of the northern borderlands of Tibet. A Prjevalsky medal was awarded to J. A. Schmidt, for his twelve geodetical expeditions to different parts of Central Asia and Siberia; and one to Dr. H. A. Fritsche, for his magnetic measurements in China, Mongolia, Siberia, and Russia. Two small gold medals were awarded to F. F. Müller, for his magnetical work in East Siberia; and to A. A. Lebedintseff, for his researches into the chemical composition of water in the Black and Azov Seas. Eighteen silver medals were awarded for various works of lesser importance.

A FULL description of the cell invented by Dr. W. W. Jacques, for the production of electricity by the consumption of carbon, is given in the July number of the *Engineering Magazine*, by Mr. G. H. Stockbridge. The apparatus consists of a pot of pure iron surrounded by a suitable furnace and containing caustic soda, in which hangs a rod or cylinder of carbon. The carbon must be in such a state that will serve as a good conductor of electricity. Gas, carbon, and charcoal are available without special treatment; but anthracite coal has to be baked to give it the requisite conductivity, and bituminous coal needs, for the same purpose, to have some of its hydrocarbons driven off. Commercial caustic soda can be used without expelling the usual impurities. Air is forced through the caustic soda by means of an air-pump. To set the cell in operation the furnace and its enclosed generator containing the caustic soda is brought to a temperature of 400° to 500° C., and the air-pump is put in action. The caustic soda takes up oxygen from the air, and releases it at the carbon. The carbon is attacked by the oxygen, and suffers a gradual consumption as long as the operation continues, an electric current being produced as a result of the action, the poles being the iron pot and the carbon rod. Some electricians say the current is only a thermo-electric one. The cell is said to have an efficiency of eighty-five or ninety per cent. This efficiency does not, however, take into account the expenditure of heat for maintaining the cell at a suitable temperature, or of the power used in running the air-pump which supplies it with oxygen. Dr. Jacques' cell is an interesting addition to the list of others devised to obtain electricity as a direct result of the consumption of carbon; but whether it will become of practical value, cannot yet be decided.

IT seems as if the Boltzmann-Maxwell distribution of the kinetic theory of gases is likely to become an everlasting bone of contention. A short time ago we chronicled in these columns an attack on Maxwell's original proof by M. Bertrand in the *Comptes rendus*, on the ground that the proof assumed independence of the frequencies of distribution of the velocity-components of a molecule of the gas resolved in three directions at right angles. This paper called forth a rejoinder from Prof. Boltzmann, inviting M. Bertrand to examine Maxwell's later proofs. M. Bertrand replied that he considered these even worse than the first. Dr. Carlo del Lungo, writing in the *Atti dei Lincei* in defence of the proof first objected to by M. Bertrand, now endeavours to prove that the assumed independence of distribution of velocities is a necessary consequence of the principles of conservation of momentum and of energy. It certainly seems impossible to give a rigorous proof of the Boltzmann-Maxwell distribution without making *some* assumption beyond the ordinary principles of pure dynamics (*e.g.* the assumption that the only intermolecular forces are those due to impact). But Dr. del Lungo also upholds the view that the general evidence in favour of the law lies in the fact that the distribution in question satisfies so many conditions which are not satisfied by any other distribution, and which represent more or less closely the phenomena present in gases.

DR. A. LAMPA, working in the laboratory of Prof. Franz Exner, has determined the refractive indices of a number of substances for electric waves of very small length. The experiments, which form the subject of a communication to the *Wiener Sitzungsberichte*, were made with electromagnetic radiations of 8 mm. wave-length; this number being ascertained both from the dimensions of the excitor and by diffraction observations. The wave-length in question corresponds to the frequency $N = 37{\cdot}500 \times 10^6$, and Dr. Lampa gives the following values for the index n: Paraffin, 1·524; ebonite, 1·739; crown glass, 2·381; flint glass, 2·899; sulphur, 1·802; benzole, 1·767; glycerine, 1·843; oil of turpentine, 1·782; oil of vaseline, 1·626; oil of almonds, 1·734; absolute alcohol, 2·568; and distilled water, 8·972.

M. L.-A. MARMIER, of the Pasteur Institution, has communicated to the Société Française de Physique the results of an interesting series of experiments on the action of currents of high frequency on microbian poisons. It had been previously announced by MM. d'Arsonval and Charrin that such currents affect these poisons to a considerable extent, and M. Marmier has examined whether this modification is a new phenomenon, or merely a secondary result of well-known effects of the current. It is found that the alteration in question only occurs when the liquids are allowed to become heated to a temperature which would alone suffice to modify the poisons. When

the liquids are kept cool by suitable precautions, no modification takes place, and M. Marmier concludes that currents of high frequency do not themselves affect microbian poisons. The experiments were performed on the toxin of diphtheria, that of tetanus, and the venom of the cobra snake.

IN the June number of the *Annalen der Hydrographie* there is an interesting discussion, by H. Haltermann, of the occurrence of St. Elmo's Fire at sea, based upon observations in the log-books received at the Deutsche Seewarte. The tables contain full details as to position, conditions of weather, &c. During more than 77,000 days of observation, the phenomenon was observed 164 times, 87 times in north, and 77 times in south latitude. Its occurrence differs very considerably in different parts of the ocean, *e.g.* in the ten-degree square lying between the equator and 10° N. lat., and between 20° and 30° W. long., St. Elmo's Fire was observed about three times per 1000 days, while in the two squares lying between 50° and 60° S. lat. and 60° and 80° W. long. it occurred six times per 1000 days. The more frequent occurrence at sea than on land is attributed to the fact that the accumulating electricity is more easily conducted by the numerous objects projecting into the air over the land.

ON July 2, Prof. Wiesner presented to the Vienna Academy of Sciences an investigation on the important relation of plant-life to photo-chemical climate, based on observations made at Vienna, Buitenzorg (Java), and Cairo. The measurements of the chemical intensity of light were made by a process corresponding in principle to the photographic method of Bunsen and Roscoe. The following are the principal results arrived at: (1) The greatest chemical intensity of light at Vienna amounted (in Bunsen-Roscoe units) to 1·500, and at Buitenzorg to 1·612. (2) The average ratio of the noon intensity to the daily maximum at Vienna was as 1 : 1·08, and at Buitenzorg as 1 : 1·22. (3) At Vienna the yearly noon intensity varied in the proportion of 1 : 214, and at Buitenzorg, in the proportion of 1 : 124. (4) As a rule the daily maximum at Vienna occurred about noon, and at Buitenzorg in the late forenoon. This explains the relatively high maxima at Vienna, and the relatively low maxima of Buitenzorg. In clear or uniformly cloudy weather, the maximum occurred generally at noon at both places. (5) At Cairo a strong depression of the daily curve of intensity was observed at noon, during a perfectly clear sky. This depression was also observed on rare occasions at Vienna, but to a smaller extent. (6) At Buitenzorg the chemical intensity of light was generally greater in the forenoon than in the afternoon. At Vienna this excess was greatest in June and July; the morning intensities were generally higher than the corresponding evening intensities, even when the sky was similarly clouded.

GENERAL PYEVTSOFF, who has had great experience in the measurement of altitudes in Central Asia with the barometer, publishes in the *Memoirs* of the Russian Geographical Society a very valuable paper on barometrical levellings, in which he points out once more the degree of precision that can be obtained from such measurements. He discusses separately the errors in the calculated altitudes which are due to disturbances in the atmosphere resulting from cyclonic and anticyclonic air-movements, to the error in the determination of the average temperature of the air between the two stations at which the barometer has been simultaneously observed, &c., and he gives their relative importance under different circumstances. The most valuable part of the author's inquiry is the comparison which he has made between the real differences of altitudes of twenty-eight different meteorological stations, situated at distances of from 67 to 270 miles from each other, and the altitudes which are obtained day by day from a comparison of the readings of the barometer at the stations, taken in pairs. It appears, as a rule, that if the readings on the days of great atmospheric disturbances are not taken into account, the results are most satisfactory, and that the errors, due to an unequal distribution of pressure at the two stations, seldom exceed 100 feet, and only occasionally attain 140 feet, even for stations taken so wide apart as 100 and 270 miles. As to the altitudes determined in Central Asia, they very seldom exhibit errors exceeding 300 to 400 feet, which evidently is, for separate places, a quite sufficient approximation. At the end of his memoir, General Pyevtsoff gives new tables, based on Babinet's formula, for the calculation of altitudes without the aid of logarithms, which tables combine great accuracy with rapidity, and are very practically arranged.

THE extension of the use of pure yeasts has not unnaturally caused a good deal of attention to be of late bestowed upon the most efficient methods, both for their successful preservation and transmission. Pure yeast cultures can be purchased much as any other article of commerce at the present day, but a great deal depends upon how these so-called stock yeasts can be stored. Experience has shown that, in general, solutions of cane-sugar answer far better for this purpose than wort-gelatine or infusions of wort. In saccharine solutions, yeasts have been preserved in perfect condition for as long as fourteen years. There are, however, exceptions to this rule, for Hansen reports that the *Saccharomyces Ludwigii* dies off in from two to three years when kept in saccharine solutions; whilst Dr. Holm has quite recently described a particular variety of yeast obtained from some Jamaica molasses, which could not be persuaded to exist beyond twelve months in such solutions, whilst in wort-infusions it was still alive after the lapse of two and a half years. With these exceptions, however, saccharine solutions answer the purpose perfectly; but it is of great importance that vessels containing these stock yeasts, whilst occupying very little space, should obviate as far as possible the evaporation of the contents. This evaporation has caused no little trouble in the past; but, thanks to an ingenious device of Jörgensen's, it appears to be happily overcome. The apparatus employed has been recently described by Dr. Holm, to whom the conduct of the experiments involved in determining this point were entrusted, and his paper appears in the *Centrablatt für Bakteriologie*, part ii. Not only may the special flasks described be used for liquids, but they have been found also of great service in preserving gelatine cultures from drying up, and Dr. Holm tells us that, even six months after its preparation, the gelatine in these flasks still retained its soft consistency, and was not in this respect distinguishable from freshly prepared gelatine. This should overcome a difficulty with which bacteriologists are frequently troubled.

IN the summer of 1893, two of von Rebeur-Paschwitz's horizontal pendulums were erected at the observatory of Charkow, and the reports on the observations made with them are being issued by Prof. G. Lewitsky, now director of the Dorpat Observatory. The first pamphlet, consisting of sixty-three pages, is one of the most valuable contributions to the study of earthquake-pulsations so far published. It contains detailed records of 139 series of pulsations between August 4, 1893, and October 9, 1894, the time and amplitude of each marked phase being given, as well as the epochs of the beginning and end of the movement. The duration of some of the disturbances is extraordinary. Thus, the oscillations due to the Greek earthquakes of April 20 and 27, lasted for 14h. 50m. and 12h. 35m. respectively, and those from the Constantinople earthquake of July 10 for 13h. 26m. In these cases, however, the epicentre was not at a great distance. Turning to others of remoter origin, we find that the Japanese earthquake of March 22

affected the pendulum for 10h. 14m., and the Venezuelan earthquake of April 28 for as much as 10h. 30m.

WE notice in the Moscow geographical review, *Earth Knowledge* (*Zemlevedenie*), a very valuable paper, by M. Alboff, "On the Vegetation of West Caucasia." The paper is an introduction to his recently-published great work, "Prodromus Floræ Colchidæ."

THE Director of the Geodynamic Section of the Observatory of Athens has sent us the *Bulletin Mensuel Seismologique* for February, March, and April of the present year. The fact that these three numbers contain records of 147 earthquakes in Greece and the Ionian Islands, shows what an admirable field for study is placed before Dr. Papavasilion. Many of these shocks occurred in districts which have been recently visited by severe earthquakes, no less than sixty-six having been felt in Zante alone.

THE *Proceedings* of the Edinburgh Mathematical Society for the Session 1895–96 have just been published. Among the papers is one having an application to optical instruments, viz., "A summary of the theory of the refraction of thin approximately axial pencils through a series of media bounded by coaxial spherical surfaces, with application to a photographic triplet, &c.," by Prof. Chrystal. Prof. G. A. Gibson contributes to the volume an interesting descriptive review of Prof. Cantor's "Vorlesungen über Geschichte der Mathematik," with special reference to the rise of the infinitesimal calculus, and the Newton-Leibnitz controversy. There is also a paper on "The number and nature of the solutions of the Apollonian contact problem," by Mr. R. F. Muirhead, and others on "Symmedians of a triangle and their concomitant circles," by Dr. J. S. Mackay, and "On deducing the properties of the trigonometrical functions from their addition equations," by Mr. Muirhead.

FOUR parts of the *Transactions* of the Royal Society of Edinburgh, embracing the period 1893–95, are among recent publications. As we regularly print reports of papers read at the Edinburgh Royal Society, it is unnecessary to do more now than refer to a few of those published in the present parts of the *Transactions*. A paper, by Mr. Aitken, on dust particles, and the relation between them and meteorological phenomena, appears in part iii. of vol. xxxvii.; which also contains papers on the fossil flora of the South Wales coal-field, by Mr. R. Kidston, and on the variations of the amount of carbonic acid in the ground-air, by Dr. C. Hunter Stewart. The following part of the same volume has papers on the partition of a parallelepiped into tetrahedra, by Prof. Crum Brown; on the manganese oxides and manganese nodules in marine deposits, by Dr. John Murray and Mr. Robert Irvine; and on the chemical and bacteriological examination of soil, with special reference to the soil of graveyards, by Dr. J. Buchanan Young. The greater portion of part i. (vol. xxxviii.) is taken up with Dr. H. R. Mill's elaborate paper on the distribution of temperature in the Clyde Sea area. The paper is accompanied by thirty-two plates, most of them containing several coloured diagrams, and it is altogether a monument of painstaking observation and careful work. Among the remaining contents of the same publication are papers on bird and beast in ancient symbolism, by Prof. D'Arcy Wentworth Thompson, jun.; two glens (Glen Aray and Glen Shira), and the agency of glaciation, by the Duke of Argyll; and on the relation between the variation of resistance in bismuth in a steady magnetic field, and the rotatory or transverse effect, by Mr. J. C. Beatie. In part ii. of vol. xxxviii. are two extremely important papers, one on specific gravities and oceanic circulation, by Dr. Alex. Buchan; and the other on deep- and shallow-water marine fauna of the Kerguelen region of the great Southern Ocean, by Dr. John Murray. Dr. Buchan's paper is accompanied by nine maps, showing the specific gravity of the oceans at observed temperatures from the surface to a depth of 2000 fathoms. An immense amount of material has thus been brought together for the benefit of oceanographers.

AN important source of vanadium compounds has lately been discovered in South America. In the high plateaus of the Andes, at a height of about 16,000 feet, there exists a mine of anthracite containing vanadium. The coal from this mine, which is easily worked, burns easily, leaving about two per cent. of ash. This ash contains one-seventh to one-quarter of its weight of vanadium, besides some silver, with traces of zirconium and platinum. The extraction of the vanadium on the large scale has been accomplished by M. K. Hélouis, who has applied it to the preparation of aniline black, to the colouring of porcelain, and in metallurgy. The vanadium used by M. Moissan in the preparation of vanadium carbide came from this source.

IN the current number of the *Berichte* there is an account, by Mr. O. Piloty, of a new method of preparing the salts of hyponitrous acid, for which it is claimed that the yield is in advance of all methods previously described. Hydroxylamine hydrochloride, by treatment in alcoholic solution with sodium ethylate and benzene-sulphonic chloride, is converted into benzene sulphonehydroxylamine, $C_6H_5.SO_2.NH.OH$, and this, on treatment with concentrated potash solution, gives the potassium salts of benzene-sulphonic and hyponitrous acids, which can be separated without difficulty. The mechanism of the reaction is precisely analogous to the production of hyponitrite from potassium hydroxylamine mono-sulphonate, discovered by Divers and Haga (*Jour. Chem. Soc.*, 1889, p. 760). In a subsequent note, referring to the preliminary note by Hantzch, stating that anhydrous hyponitrous acid can be obtained, Mr. Piloty describes the results obtained by him in this direction. Silver hyponitrite, suspended in ether and treated with hydrogen chloride, gives silver chloride and a solution of $H_2N_2O_2$ in ether. Rapid evaporation of the ether causes the deposition of the acid as an oil, which solidifies to a crystalline mass in a freezing mixture. As might be expected, both the oil and solid possess highly explosive properties. Of the numerous isomerides of the formula $H_2N_2O_2$ theoretically possible, this is the second to be isolated, the nitramide NH_2NO_2 of Thiele and Lachman being the first.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus*, ♀) from North Africa, presented by Mr. E. G. Walls; a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Mr. P. Clarke; two Macaque Monkeys (*Macacus cynomolgus*, ♂ ♀) from India, presented by Mrs. Williamson; an Ocelot (*Felis pardalis*) from Trinidad, presented by Mr. H. O. Nicholls; a Black-tailed Flower-Bird (*Anthornis melanura*) from New Zealand, presented by the Hon. Walter Rothschild; a New Zealand Parrakeet (*Cyanorhamphus novæ-zealandiæ*) from New Zealand, presented by Miss A. Malcolm; a Bare-eyed Cockatoo (*Cacatua gymnopis*) from South Australia, presented by Mrs. M. E. Huntley; a Boobook Owl (*Ninox boobook*) from Australia, presented by Dr. R. Broom; a Raven (*Corvus corax*), British, presented by Mr. William Soper; a Rook (*Corvus frugilegus*), British, presented by the Rev. A. Greaves; six Purplish Death Adders (*Pseudechis porphyriaca*), three Brown Death Adders (*Diemenia textilis*), six Short-headed Death Adders (*Hoplocephalus curtus*) from Australia, a Yellow-headed Conure (*Conurus jendaya*) from South-east Brazil, deposited; six Garter Snakes (*Tropidonotus ordinatus*), six Dekay's Snakes (*Ischnognathus dekayi*), three Spotted-headed Snakes (*Ischnognathus occipito-masculatus*),

three Grass Snakes (*Cyclophis vernalis*), a Hog-nosed Snake (*Heterodon platyrhinos*) from Montreal, received in exchange; two Patagonian Cavies (*Dolichotis patachonica*), two Ypecaha Rails (*Aramides ypecaha*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

NOVEMBER METEORS.—With the July number of *Monthly Notices R.A.S.* a circular is issued by G. Johnstone Stoney, calling the attention of astronomers to the approach of the great secular maximum of the Leonids, which is due about 1899 or 1900. It is probable that this swarm was drawn into the solar system by the planet Uranus about February or March A.D. 126, and careful observations during the next few years may furnish materials for confirming or rejecting this hypothesis. Photography should be employed as widely as possible, and wherever practicable the time of appearance of each meteor recorded. Accurate simultaneous observations from different stations will be of exceptional use. The radiant-points and times of apparition of all meteors should be exactly noted, commencing a few nights before, and continuing some nights after, November 14 and 15.

PLUMB-LINE DEVIATIONS.—M. Messerschmitt, who has been for some time engaged in the determination of latitude and azimuths of a series of points in the Swiss Triangulation, has communicated (*Ast. Nach.*, No. 3365) the results of his most recent investigations. It may be recalled that M. Messerschmitt's first determinations were made in West Switzerland, and these were followed by further researches in the north of the country, which corroborated his previous results. The present paper is concerned with observations made on a line drawn approximately north and south through the centre. Collecting his results into a table showing the difference between geodetic and astronomical latitude, and arranged in order of increasing distance from the equator, a systematic deviation from the vertical is clearly shown. In the midst of the mountains (around Andermatt for example) these deviations are quite small. Going south they increase rapidly, and attain a negative maximum of 20″ (astronomical—geodetic) towards Lugano. A positive maximum occurs about Goschenen, the entrance to the Gotthard Tunnel; and still further north, the difference diminishes again, and changes sign about the latitude of Zürich. Schaffhausen shows again the position of negative maximum. The position of the mountain chains generally explains these variations.

An investigation, founded on these deviations of the plumb-line, of the form of the surface of the earth for a meridian length of about 200 km. through the Gotthard district, discloses the fact that the ellipsoid sinks everywhere below the geoid. Selecting as a zero point that position where no deviation from the vertical exists (47°·1 15′ lat.), the greatest difference between the two surfaces occurs near Airolo (the southern exit of the tunnel), where it amounts to nearly five metres. Going southwards from this point the surface sinks gradually, and approaches the ellipsoid before the valley of the Po is reached.

THE HAMBURG OBSERVATORY.—Prof. Rumker's report of the observatory work during the year 1895, shows that the activity of the various departments is fully maintained. The observations with the equatorial have mainly consisted in deriving the positions of small planets and comets, and of the fainter stars with which the nebulæ, whose places have been published in a communication from the observatory, have been compared. With smaller instruments attention has been given by Dr. Hänig to variable stars and occultations by the moon. With the meridian instrument, in addition to observations required for the accurate distribution of time signals, arrangements have been made for observing stars in the degree 80–81 N. Decln. down to 9·3 mag. In addition to this varied work, the attention of the staff has been called by Dr. Auwers and others to discrepancies between the places of stars in the Hamburg catalogue, and those recently obtained in the "Astronomischen Gesellschaft" zone catalogue. This has necessitated much searching of old records, and in some cases the detection of errors, which will be published in a communication from the observatory.

THE DUNSINK OBSERVATORY.—The seventh part of the astronomical observations and researches made at Dunsink, and published under the direction of Prof. Rambaut, contains the meridian places of 717 stars, of which upwards of 2000 observations have been made. These stars have been selected on account of suspected large proper motions, and the observations, interrupted as they have been from several causes, have been spread over eleven years. But, nevertheless, the accuracy maintained throughout is of a very high degree. From an examination of the separate results, the probable errors in R.A. and Declination are, respectively, $\pm$ 0″·037, and $\pm$ 0″·505. This error is probably increased by the uncertainty of the proper motion in many cases, and does not fully express the accuracy of the work. The Pistor and Martin's meridian circle, with which the observations have been made, has been frequently reversed in the course of the work, and the determination of latitude, on which great care has been bestowed, is slightly different in the two positions. With Clamp West the resulting latitude is 53° 23′ 13″·05, and with Clamp East three-tenths of a second less. The value used in the final reduction is 53° 23′ 13″·00, and the results, it is believed, coincide very closely with Auwers' fundamental system. The cause of this systematic difference in the latitude, however, has not been satisfactorily explained.

OBSERVATORY OF MOSCOW.—The last issue of the *Annals* of this Observatory (series 2, vol. iii. part 2, 1896) contains several papers of general interest. The director, W. Ceraski, contributes the following articles: (1) "Photometry of the star cluster χ Persei," in which he gives the measures of the magnitude of seventy stars of the group, determined with a Zollner photometer on a 10-inch refractor. One star he finds to be variable, and recommends its further study. (2) "Observations of eclipses of Jupiter's satellites without photometric appliances," using eye estimates of relative magnitude compared with some neighbouring star of known brightness. (3) "On the temperature of the sun," in which he gives the inferior limit to be about 3500° C. (4) "A new method for the electrical comparison of pendulums."—P. Sternberg discusses the photographs he obtained during the transit of Mercury on May 9, 1891, and also contributes an important description of his determination of the variation of latitude at Moscow.—B. Modeston gives a full description of the calculation of double-star orbits by the methods of Kowalski and Encke respectively. —S. Blajko, as the result of thirteen photometric measures of the magnitude of Mira Ceti during the winter of 1894–5, finds evidence of a secondary maximum in its light curve, occurring about a month previous to the highest maximum, the magnitudes at the secondary and principal maxima being about 3·5 and 3·16 respectively.

THE SOLAR ECLIPSE OF APRIL 16, 1893.

M. DESLANDRES has now issued his report on the work accomplished by the French expedition to Fundium, Senegambia, for observations of the total solar eclipse of April 16, 1893. Some of the results obtained have already been made known, and these are now brought into connected order and discussed. A full account is also given of the general objects and organisation of the expedition. The programme decided upon included the photography of the corona, a photographic study of the coronal spectrum, especially in the ultra-violet, and a spectroscopic study of the movements of the corona.

The report is of special importance in view of the approaching eclipse, for the reason that reference is made to several points which may serve as a guide in future operations. For example, M. Deslandres' experience indicates that for the corona pictures plates of moderate sensitiveness give better results than the plates of greater rapidity. Another practical suggestion is that at least two cameras should always be employed in the search for an intra-mercurial planet; M. Deslandres found it impossible to determine whether certain spots on the single plate which he obtained represented stars or photographic defects.

The general results relating to the coronal spectrum are thus stated: (1) The continuous spectrum of the corona, which forms the greater part of its light, is most intense on the red side, relatively to the spectrum of the disc, and the difference appears to become greater as the point considered is further removed from the photosphere. (2) The spectrum of dark lines, under very favourable conditions, did not appear at 5′ from the sun's limb; at this height the light diffused by the coronal particles is still too feeble with respect to their own light. (3) The luminous gases of the corona, indicated by the fine lines, have not the same intensity or composition in different parts of

the corona, or at different heights; further, they most frequently do not correspond to elements known upon the earth.

Special interest attaches to the investigation of the rotation of the corona by observing or photographing the displacement of lines in the spectrum at some distance from the limb on each side of the equator. No photographic impression was secured with the fourth order spectrum of a diffraction grating, adjusted for H and K, and, although the eclipse occurred at a maximum of sun-spots, 1474 K was too feeble in the second order spectrum to permit any trustworthy measures to be made visually. A successful photograph of the H and K lines was obtained, however, with a 3-prism spectroscope attached to a 6-inch refractor, one half of the slit being exposed on the west and the other on the east side of the corona. The measured velocity of 6·8 km. per sec. has led M. Deslandres to conclude that the equatorial part of the corona moves very nearly with the same angular velocity as the photosphere. This result must be received with caution until confirmed by further researches, as the photographs taken at the same moment by Mr. Fowler give no indications of the presence of H and K in the true coronal spectrum. It is pointed out that this research may be simplified in future by making only one exposure, placing the slit radially, so that the velocities may be determined from the inclination of the lines, as in the recent researches on Saturn's rings.

In the last chapter of the report, various hypotheses as to the nature of the solar atmosphere are reviewed, and an electrical theory is propounded. It is pointed out that, notwithstanding the diversity of appearances, there is really a great similarity between the solar and terrestrial atmospheres, and the report ends as follows: "Terrestrial meteorology and solar physics, which are separated by the necessity for the division of work, are in reality connected sciences, which, by the nature of things, ought to be studied together."

THE RÖNTGEN RAYS.[1]

PROF. RÖNTGEN, of Wurzburg, at the end of last year published an account of a discovery which has excited an interest unparalleled in the history of physical science. In his paper read before the Wurzburg Physical Society, he announced the existence of an agent which is able to affect a photographic plate placed behind substances, such as wood or aluminium, which are opaque to ordinary light. This agent, though able to pass with considerable freedom through light substances, such as wood or flesh, is stopped to a much greater extent by heavy ones, such as the heavy metals and the bones; hence, if the hand, or a wooden box containing metal objects, is placed between the source of the Röntgen rays and a photographic plate, photographs such as those now thrown on the screen are obtained. This discovery, as you see, appeals strongly to one of the most powerful passions of human nature, curiosity, and it is not surprising that it attracted an amount of attention quite disproportionate to that usually given to questions of physical science. Though appearing at a time of great political excitement, the accounts of it occupied the most prominent parts of the newspapers, and within a few weeks of its discovery it received a practical application in the pages of *Punch*. The interest this discovery aroused in men of science was equal to that shown by the general public. Reports of experiments on the Röntgen rays have poured in from almost every country in the world, and quite a voluminous literature on the subject has already sprung up.

In view of the general interest taken in this subject, I thought that the Röntgen rays might not be an unsuitable subject for the Rede Lecture.

Before discussing these rays themselves, I think it may perhaps make matters clearer if I call your attention to one or two of the phenomena which accompany the discharge of electricity through gas at a low pressure. I have here a bulb from which the air has been taken until the pressure has been reduced to about 1/10000 part of the atmospheric pressure. When the electric discharge passes through this bulb you see that there is considerable luminosity in the gas in the bulb, except in a region round this terminal—the negative one; this region, where the luminosity is so deficient, is called the negative dark space. In this bulb there is no phosphorescence on the glass, and I may say no emission of Röntgen rays. If I were still further to reduce the pressure of the gas in this bulb, this dark space would expand and encroach on the luminous part of the discharge, and would, when the pressure got very low, reach the walls of the tube; the expansion of the dark space diminishes the luminosity in the gas, but we find that where the dark space reaches the glass of the tube the glass itself becomes luminous, until finally at very low pressures we get to the state of things shown by this tube, where the luminosity is all on the glass, and little or none is to be observed in the gas. Röntgen rays are produced by this bulb, though not by the other.

There is one feature in this tube to which I must call your attention: you see that there is a shadow on part of the tube; this shadow is thrown by a mica cross fixed between the negative electrode and the wall of the tube, and if we observe the shape of the shadow we see that any point of the tube is in shadow if the line joining that point to the negative electrode passes through the mica cross. We thus conclude that we have something starting from the negative electrode, travelling in straight lines, and producing phosphorescence when it reaches the glass, and, further, that this something is stopped by the mica cross. This something which travels in straight lines from the kathode is called the kathode rays: these rays are of great interest in relation to the subject of this lecture, for the kathode rays seem to be the parents of the Röntgen rays. Let me call your attention to the effect produced by a magnet on these rays: you see that when the magnet is brought near, the shadow of the cross is displaced; this shows that the direction of the rays casting the shadow have been deflected by the magnet, thus the kathode rays are deflected by a magnet. We shall see later on that the Röntgen rays, on the other hand, are not so affected. This is one of the most striking differences between the parent—the kathode rays—and the child, the Röntgen rays. The effects of the kathode rays inside the tube were discovered more than twenty years ago by Crookes and Goldstein: it is only quite recently, however, that any effects produced by these rays outside the tube have been observed. In 1894 Lenard, using a tube of the kind shown in the diagram (Fig. 1), where the kathode

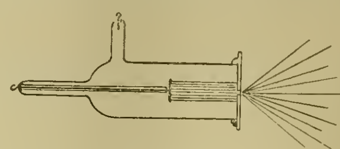

FIG. 1.

rays struck against a window made of very thin aluminium, found that if he placed outside the tube in front of the window a screen covered with a phosphorescent substance, pentadecaparatolyketon, it became phosphorescent; he found, further, that a photographic plate placed behind the window was affected—nay, that this plate was affected even though he placed in front of it a plate of aluminium or a thin quartz plate—in fact, he took a photograph through aluminium and quartz; he thus obtained two of the most prominent phenomena shown by the Röntgen rays. In fact, we know from the researches of Röntgen that the Röntgen rays must have been present and played a part in these experiments. Lenard himself ascribed the effects he observed to kathode rays which had penetrated the aluminium window, and indeed it would seem that something in addition to the Röntgen rays must have been present, as Lenard found that the position of the phosphorescent patch was affected by a magnet, while the Röntgen rays themselves are, as we shall see, not influenced by such an agent.

I now come to the consideration of the Röntgen rays themselves, and shall endeavour to repeat some of the experiments by which Röntgen established their existence. The apparatus consists of a tube exhausted to such a low pressure, that when the electric discharge passes through it there is an abundant supply of kathode rays; these rays strike against a metal plate in the bulb. This metal plate is not essential for the production of the rays, and was not present in the bulbs used by Röntgen; it, however, considerably increases the efficiency of the bulb.

When the electric discharge passes through this bulb, the region round it is the seat of some very remarkable phenomena. I have here a screen coated with a phosphorescent substance,

[1] The Rede Lecture, given at the University of Cambridge, on June 10, by Prof. J. J. Thomson, F.R.S.

potassium platinocyanide; though this screen is opaque to ordinary light, you will see that it phosphoresces when placed in the neighbourhood of the bulb. This phosphorescence is due to something radiating from the bulb, because when I place this piece of metal between the bulb and the screen, a sharp shadow of the metal is thrown on the screen. The metal is opaque to these radiations. If, however, I place a piece of wood, about an inch thick, between the bulb and the screen, you will hardly be able to see a shadow; so that this board, though opaque to ordinary light, allows those rays to pass through with considerable freedom. The lighter the substance the more easily is it penetrated by these rays; thus the very light metal aluminium is very transparent, as you will see by the poor shadow it casts upon the screen. This property has been used to detect real gems from paste, as the diamond, consisting of the light element carbon, is much more transparent than an artificial one made of heavy silicates. Since light objects are, roughly speaking, transparent, while the heavy ones are opaque, if we have a mixture of heavy and light objects between the screen and the bulb, the heavy ones will throw a shadow, the lighter ones will not. We can thus detect dense objects even when surrounded by opaque ones, provided the latter are light. [Experiments throwing shadows of jewellery in cases, hands, &c., upon the screen.] Prof. Lodge has in this way been able to see through a yard of timber. We seem here to have the realisation of Sam Weller's aspiration after an optical arrangement which would enable one to see through "a flight of stairs and a deal door."

I will now endeavour to show that in order to have Röntgen rays you must have kathode rays to start with. I will produce in the bulb, which I have used for the production of the Röntgen rays, a discharge of another kind, viz. an electrodeless discharge in which the discharge, instead of travelling between metallic terminals in the gas, travels round a closed circuit in the gas. In this way we have no kathode and no kathode rays; you see that though a bright discharge passes through the bulb, far brighter than in the previous case, no luminosity is produced on the screen.

One very remarkable property discovered by Röntgen of these rays, is that they are not bent when they pass from one medium to another. We can show this in the following way. I place in front of the bulb this thick plate of metal, in which a vertical slit has been cut; the metal stops the rays, so that we get on the screen a bright luminous vertical band. Now I place between the slit and the screen this wooden prism, which covers up the lower, but not the upper, half of the slit; if the rays which came through the slit were refracted, then the lower part of the bright band would no longer be in the same straight line as the upper part. You see, however, that the two halves still remain on the same line; the only effect produced by the wooden prism has been to make the lower half somewhat dimmer than it was before.

Again, these rays are not deflected by a magnet; to prove this, we throw the shadow of two brass tubes on the screen, and observe the shadows before and after a horse-shoe magnet has been introduced into the tubes; you see that no appreciable effect is produced by the introduction of the magnet.

The absence of refraction leads us to expect that there would be little regular reflection of the Röntgen rays, and this conclusion has been confirmed by numerous experiments. At grazing insistence, however, Joly of Dublin has been able to detect a small amount of regular reflection. Though there is but little regular reflection there is an appreciable amount of what, to avoid any speculation as to its nature, has been called by Sir George Stokes "diffuse return" of the rays; this was discovered by Röntgen himself, and is rendered very evident by an experiment of Lord Blythswood We do not know yet, however, whether the rays coming off from the metal plate are of the same kind as those which fall upon it, or whether they are slightly different. If they are of the same kind, then the effect would resemble the diffuse reflection from a piece of ground glass; if they are different, it would indicate that the piece of metal illuminated by these rays became itself a source of rays not quite of the same kind as those which fall upon it, just as when a solution of quinine is exposed to the invisible ultra-violet light it emits not ultra-violet light like that which fell upon it, but visible blue light. This point might be settled by measurements of the rates of absorption of the incident and "diffusely returned" light.

That the Röntgen rays are not all of the same kind, has been shown in several ways, of which, however, I have only time to mention one. Mr. McClelland, working in the Cavendish Laboratory, found that if he took a plate of tinfoil and a layer of water, and adjusted the thicknesses so that they exerted the same absorption on the Röntgen rays given out from one bulb, they did not necessarily produce the same absorption in the rays from another bulb, showing that the rays from the one bulb were not the same as those from the other.

Röntgen discovered that the rays not only made certain substances phosphorescent, but that they affected a photographic plate; so that if we replaced the phosphorescent screen in our experiment by a photographic plate, we should get a permanent impression of the picture, which would be thrown on a phosphorescent screen placed in the position of the photographic plate. To obtain these photographs all that is necessary is to protect a photographic plate from ordinary light by thick cardboard or aluminium, and place the object to be photographed between the bulb and the plate; after an exposure varying with the nature of the object and the state of the bulb, photographs of the kind which are now so well known can be obtained.

One very marked feature of these photographs is the sharpness of the detail; this shows that the origin of the rays must be confined to a comparatively small region. If these rays came from an area comparable with that occupied by the phosphorescence on the walls of the bulb used to produce the rays, the luminosity from one part of the screen would throw one pattern on the screen, while the rays from another portion would throw another pattern; the superposition of these patterns would produce a blurred image. To illustrate this point, I have here two photographs of the same thing—one taken by the Röntgen rays, the other taken by an incandescent lamp with walls of frosted glass, of about the same size as the bulb used to produce the Röntgen rays, and placed in the same position; you see that the photograph taken by the Röntgen rays is quite sharp, while that taken by the electric lamp is much blurred. This shows that the Röntgen rays do not come from an area nearly so extended as the phosphorescent part of the glass. We can investigate the place of origin of these rays in various ways, by observing the law of diminution with the distance of the effects due to these rays, by taking pin-hole photographs, by observing the direction of the shadows cast by a series of opaque bodies; the result of such observations shows that Röntgen rays are produced when the kathode rays strike against a solid obstacle. Cases have been observed by Lord Blythswood and by Rowland, which seem to show that this is not the only source of these rays.

The experiments made on these ray have not led to any result absolutely decisive as to their nature, but we can profitably discuss the question whether the facts known about these rays oblige us to regard them as due to a new form of energy, or whether they are consistent with these rays being a variety of some form of energy already known to us; before calling in a new form, we ought to be quite sure that it is necessary to abandon the old. The rectilinear propagation of these rays, their powers of producing phosphorescence and of affecting a photographic plate, their insensibility to a magnet, suggest that of the old forms of energy light is the one to which these rays are most closely allied. We are acquainted with so many varieties of light (by light I mean transverse vibrations propagated with a definite velocity) with such widely different properties, that we can well contemplate the existence of other kinds with still different properties. We know, for example, the ultra-violet light of very small wave-length, the subject of classical researches by Sir George Stokes, which, though it affects a photographic plate, does not affect the retina, and passes through bodies with such difficulty that the most ultra-violet kind is quenched after passing through a few millimetres of air; then we have the visible light able to affect the retina, and able to pass through great lengths of some substances which are opaque to the ultra-violet rays though stopped by very small thicknesses of others; then we have the longer waves of radiant heat given out by a hot body below the temperature at which it becomes luminous. These are not visible, have but little effect on a photographic plate, and are able to traverse substances opaque to both ultra-violet and visible light. Then we have the waves emitted by vibrating electrical systems, which neither affect the retina nor a photographic plate, which, as Mr. Rutherford has shown, are able to traverse the walls of the houses and the bodies of the inhabitants of about three-quarters of a mile of a densely populated part of Cambridge, and which are so different

in properties from ordinary light that it required the genius o Clerk-Maxwell to recognise them as light at all. I shall have to call your attention to another kind of light, discovered lately by Becquerel. It will doubtless be urged that widely as these kinds of light differ from each other in some respects, they all are bent when they pass from one substance to another, while the Röntgen rays, as we have seen, are not refracted. This objection to the possibility of the Röntgen rays being a kind of light, formidable as it appears at first sight, loses all its force when more closely examined. We know cases in which light passes through substances without being refracted; thus Kundt found that certain rays could pass through gold without being refracted, while other rays were bent the wrong way. Stenger has lately found that certain blue rays can pass through fuchsin, and other slightly different ones through Hofmann's violet, without being bent. Perhaps, however, the most striking testimony to there being nothing inconsistent in the idea of a kind of light which is not refracted, is afforded by one of the last investigations undertaken by von Helmholtz, and published about three years ago. Von Helmholtz investigated what, on the electromagnetic theory of light, would be the bending experienced by light of different frequencies passing through an ideally simple substance, one whose spectrum consists of only one line. The result of his investigation is shown in this curve (Fig. 2), where the abscissæ represent the frequency of the light, the ordinates the refractive index. On the part of the curve from *f* to *g*, you see that the refractive index increases as the frequency increases; this corresponds to the normal spectrum where the blue rays are more refracted than the red. After passing *b* the curve dips down; this means that the greater the frequency the less the bending, in other words, the blue rays tend to be bent more than the red. We know many instances of this, it is called anomalous dispersion. Then we get to

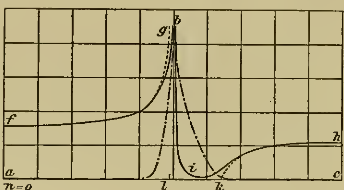

FIG. 2.

the part of the curve about *i*, where the refractive index is less than 1; that is, where the rays are bent the wrong way. We have examples of this, as Kundt has shown, in the case of gold, silver and copper; but the most interesting part of the curve for our purpose is the last part, where, after dipping below the line of no-bending for a short distance, it approaches it and practically coincides with it for all frequencies greater than *a h*; so that, on this theory there would practically be no bending for all waves whose frequency exceeds a certain value. Thus, so far from the absence of bending being a proof that the Röntgen rays are not light, this absence of bending is exactly what we should expect if these rays were light of very great frequency.

A characteristic feature of all varieties of light is the existence of polarisation, and polarisation is indisputable evidence of transversal vibration; hence, many experiments have been made to see whether any polarisation of these rays could be detected. All these experiments have practically been confined to seeing whether the Röntgen rays could traverse two plates of tourmaline more freely when the axes of the two plates are parallel than when they are crossed; there is a great difference in the transparency to ordinary light in the two cases. The results of these experiments are somewhat conflicting. Prince Galitzine and M. de Karnojitsky are of opinion that they have succeeded in detecting a slightly greater absorption of the rays when the axes are crossed than when they are parallel; on the other hand, Becquerel, Mayer, and I were not able to detect any appreciable difference in the two cases. If the result of Prince Galitzine should be confirmed, it would prove beyond cavil that these Röngten rays were light; but even if the presence of polarisation is not definitely established in this case, it does not follow that these rays can not be polarised—the methods for polarising one kind of light may not be successful when used for another. For example, a wire bird-cage will polarise the long electrical waves, but will not affect the shorter waves of radiant heat, much less those of visible light. By winding exceedingly thin wires close together on a framework, Rubens and Du Bois were able to polarise the waves of radiant heat, the wave-lengths of which are long compared with those of light. This arrangement, however, is much too coarse to polarise visible light, much less ultra-violet light. And it is possible, and indeed likely, that the structure of the tourmaline, though fine enough to polarise ordinary light, may not be fine enough to polarise the Röntgen rays.

So far, I have confined myself to showing that there is nothing in the effects known to be due to these rays inconsistent with their being a variety of light. I must now pass on to some evidence of a more positive character. Since the discovery of the Röntgen rays, Becquerel has discovered a new kind of light, which in its properties resembles the Röntgen rays more closely than any kind of light hitherto known. Becquerel found that certain uranium salts emitted, after being exposed to the sunlight, radiations which, like the Röntgen rays, could pass through plates of aluminium or of cardboard, and affect a photographic plate behind. I have here a photograph of a perforated piece of zinc, which has been taken by Becquerel's method by simply scattering over the zinc plate powdered uranium nitrate, and placing it over a photographic plate well protected from ordinary light. After a long exposure of from twenty to forty hours, the photograph now on the screen was taken. Becquerel has shown that the radiation from the uranium salts can be polarised, so that it is undoubtedly light; it can also be refracted. It forms a link between the Röntgen rays and ordinary light, it resembles the Röntgen rays in its photographic action in power of penetrating substances opaque to ordinary light, and in the characteristic electrical effect, while it resembles ordinary light in its capacity for polarisation, in its liability to refraction. The persistence of the radiation is very remarkable. Becquerel found that the potassium-platinum compound of uranium went on emitting these radiations with nearly undiminished zeal for fifteen days after it had been exposed to the sunlight. It would seem that under the influence of sunlight some change in the chemical or physical nature of the substance occurred, and that after the sunlight was cut off, the substance gradually went back to its original state, and that while doing so it emitted this peculiar radiation. The radiation from the uranium salts is of especial interest from another point of view. Sir George Stokes has shown that in the case of phosphorescence caused by sunlight or the arc lamp, the light emitted by the phosphorescent body is of longer wave-length than the light causing the phosphorescence; in the case, however, of the phosphorescence discovered by Becquerel, the light emitted is of a shorter wave-length than the incident light. The case resembles that called calorescence by Tyndall, when the body placed in a focus of dark radiant heat becomes luminous and gives out the shorter luminous waves.

From this discovery of Becquerel, we may conclude that besides the vibrations emitted by luminous bodies with which we have hitherto been acquainted, there are others having a much greater frequency and, it may be, arising in a different way.

To sum up, we may say that though there is no direct evidence that the Röntgen rays are a kind of light, there is no known property of these rays which is not possessed by one or other of the forms of light.

One of the most remarkable phenomena connected with these rays is the way in which the absorption depends upon the density of the body; if we measure the transparency of a series of bodies, we find that the order of opacity is the same as the order of their density. No other factor in the constitution of the body seems comparable in importance with density. In this respect, the relation between the opacity and the other properties of a body in the case of the Röntgen rays is simpler than that for luminous waves or electric waves. There seems no simple relation between the density of a body and its transparency to visible radiation or electrical vibration; in the case of the Röntgen rays, however, it seems the greater the density the greater the opacity. This appears to favour Prout's idea that the different elements are compounds of some primordial element, and that the density of a substance is proportional to the number of the primordial atoms; for if each of these

primordial atoms did its share in stopping the Röntgen rays, we should have that intimate connection between density and opacity which is so marked a feature for these rays.

I now pass from the consideration of the rays themselves to some of the effects they produce on bodies through which they pass.

There seems considerable evidence that the energy associated with these waves is small. I am not acquainted with any effects produced by them which involve the expenditure of an amount of energy comparable with that emitted in a second by a candle. They do not produce any appreciable rise in temperature when they fall on the thin metallic strips of a bolometer. Mr. Skinner has found that they exert no appreciable effect on the combination of hydrogen and chlorine, though this is a good test of the intensity of very faint light; and, what is more unfortunate, they do not exert any of those deleterious effects on bacteria which are fortunately associated with ultra-violet light. Some of the other effects exerted by ultra-violet light seem to be associated with these rays; thus some observers who have had undue curiosity about their bones, and have in consequence exposed their hands frequently to these rays, have found that the hand so exposed became sunburnt. There seems considerable evidence, too, that these rays are not good for the eyes, though it is difficult to disentangle any distinctly injurious effect due to the rays from the bad effect that may be produced by the straining of the eye in the endeavour to see only a faintly luminous object.

There is one property of substances which seems peculiarly suitable for testing if these rays affect the substance through which they pass; it is the property of transmitting electricity.

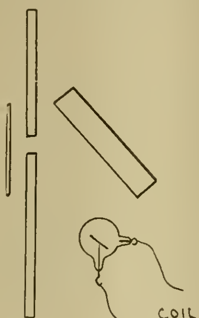

FIG. 3.

When we investigate the effect of the Röntgen rays on this property, we find the remarkable result that bodies which, when shielded from these rays, insulate to all appearance, perfectly allow electricity to pass through them when exposed to the action of these rays. I will, first of all, show an experiment illustrating this property in the case of gases which in their normal state are of all substances the most perfect insulators. The details of the experiment are shown in the diagram (Fig. 3). The coil and bulb are placed in this box, lined inside with tin-plate, and covered over the top with sheet-lead. A hole is cut in the box just over the bulb, and this hole is covered with a plate of aluminium, which is transparent to these rays. The air space between the electrodes is placed over this hole. One electrode is connected to one pair of quadrants of the electrometer, the other electrode is connected to one terminal of a battery, the other terminal of which is to earth; the two pairs of quadrants of the electrometer are connected together and with the earth, and the connection between them broken. If there is no leakage across the air space, the needle of the electrometer will remain at rest. You see it does so when the coil is not in action. As soon, however, as the coil is turned on, the spot of light moves rapidly across the scale, showing that electricity is passing across the air space. The rapidity of movement of the spot of light is a measure of the rate of leak. Now the electrical leakage produced by these rays depends on the nature of the gas. The gas I have just used was air. I will now replace the air by another gas—chlorine. Again you see the leak, but it is now much faster than before. Mr. McClelland and I have investigated the rate of leak in different gases, and we find that they can be arranged in the following order: hydrogen, coal gas, ammonia gas, air, carbonic acid gas, sulphuretted hydrogen, chlorine, mercury vapour.

That the gas itself is put into a peculiar state by the passage through it of these rays—a state which it attains for an appreciable time—is shown by the following experiment, which I described some time ago in NATURE. I have here an electrode shielded from the direct action of these rays. I charge it to a high potential, and even though the rays are on, it does not leak. I now blow some of the air through which the rays have passed on to the electrode, and you see at once we get a rapid leak. The rate at which electricity passes through the gas

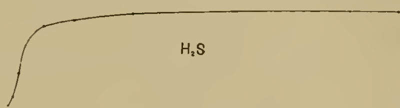

FIG. 4.

depends upon the pressure; the lower the pressure the slower the leak. Mr. McClelland and I found that for an air space of about 1 cm. the rate of leak over a considerable range of pressure varies as the square root of the pressure. In some experiments recently made by Mr. Rutherford and myself, we found that using a constant potential difference the rate of leak was smaller across a very thin plate of air than across a thicker one; it thus appears that the process of conduction through a gas is one that requires a considerable amount of room.

Another very interesting point about the rate of leak is the connection between the rate of leak and the electromotive force. This can, perhaps, be most easily understood by means of a curve (Fig. 4). The ordinate represents the rate of leak, the abscissa the electromotive force. At first, when the E.M.F. is small, the curve is a straight line, showing that the current is proportional to the electromotive force; in other words, that the conduction of electricity through the gas, like the conduction through metals and electrolytes, obeys Ohm's law. But it is

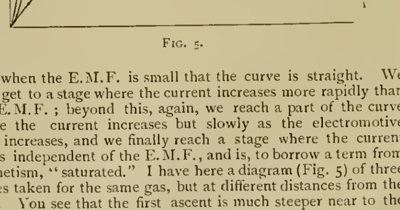

FIG. 5.

only when the E.M.F. is small that the curve is straight. We soon get to a stage where the current increases more rapidly than the E.M.F.; beyond this, again, we reach a part of the curve where the current increases but slowly as the electromotive force increases, and we finally reach a stage where the current seems independent of the E.M.F., and is, to borrow a term from magnetism, "saturated." I have here a diagram (Fig. 5) of three curves taken for the same gas, but at different distances from the bulb. You see that the first ascent is much steeper near to the bulb—that is, when the rays are strong than when it is far away and the rays are weak, and practical saturation is attained sooner when the rays are strong than when they are weak. These curves bear a remarkable resemblance to those which represent the relation between the magnetisation of a piece of iron and the magnetic force acting upon it. When the rays are strong, the curve is like that of soft iron; when the rays are weak, it is like steel.

Gases are not the only substances that conduct when trans-

mitting these rays; solids also conduct, though the conductivity obeys different laws and only lasts for a short time. The conduction through solids very closely resembles the phenomenon called "electric absorption," a well-known example of which s the residual charge of a Leyden jar.

I have here some experiments which illustrate the effect of the Röntgen rays on solids. In the first of these we have a lead cylinder with a thin base made of aluminium. At the bottom of the cylinder there is a thin layer of solid paraffin; on the top of this, and sticking to it, there is a large leaden disc, over which paraffin has been poured, so that the disc is entirely embedded in the paraffin (Fig. 6). This cylinder rests on the aluminium window in the iron chest containing the coil and the tube, this window being very much smaller than the lead plate in the paraffin. I now connect the lead plate to one pair of quadrants of a highly charged electrometer, and then connect the two pairs of quadrants together and with one of the poles of a battery of 200 small storage cells, the other pole of which is connected with the iron chest, and so with the earth. I now disconnect the quadrants from the battery, and then the quadrants from each other. There is now very little movement of the spot of light reflected from the mirror of the electrometer. When we turn on the Röntgen rays, however, the spot of light begins to move, and though the movement is small compared with that which occurred in the experiment with air, it is quite decided. The rapidity with which the spot of light moves soon, however, begins to decrease, and after a short time becomes almost

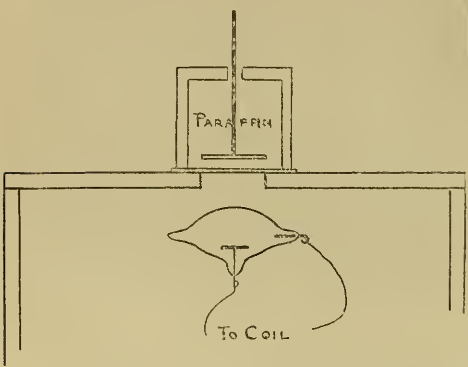

FIG. 6.

inappreciable. I now discharge the lead plate by connecting it and both pairs of quadrants of the electrometer to earth for a short time, then keeping one pair of quadrants connected with the earth, and leaving the other connected with the lead plate, we see that when the rays are off there is a very slight movement of the spot of light in the opposite direction to the original deflection; this is due to the leaking out of the "residual charge" This movement is, however, greatly increased as soon as the rays are turned on, and continues until we get quite a large deflection; "the residual charge," or polarisation in the paraffin, has then been enormously increased by the rays. The conductivity of the paraffin under these rays resembles in its properties that of the insulating sheath of a telegraph cable. In testing the resistance of such a sheath, the current passing through it does not remain constant, it rapidly falls off in intensity; and if after the electromotive force has been applied for some time it is removed, and the inside and outside of the sheath connected with the terminals of a high-resistance galvanometer, a current flows through the galvanometer, and this current is in the opposite direction to that which originally flowed through the sheath.

Ebonite shows the effect of the Röntgen rays in increasing the conductivity even better than paraffin. I have here a plate of ebonite about 1 mm. thick, coated on both sides with tinfoil. I put this on the aluminium window, and on the top of the ebonite plate I place a lead disc, which is much larger than the aluminium window; the object of this disc is to prevent the Röntgen rays from striking against the wire connected with the disc, and so discharging the disc through the air. That it is effectual in doing this, is proved by there being no leak when the rays are on, and the wire (raised to a high potential) disconnected from the disc. If we now repeat with this plate of ebonite the experiments we previously tried with the paraffin, we get similar but decidedly larger results. I may mention that different specimens of ebonite vary considerably in the magnitude of this effect. There is one variation of the preceding experiments which is of some interest. I will charge up the ebonite plate without putting the Röntgen rays on at all; on discharging, you see that the electrometer indicates that the "residual charge" is coming out. I keep discharging the disc until the residual charge is almost inappreciable. I now for the first time put on the rays, and you see that the residual charge or polarisation, which could not previously be detected, now becomes quite marked. These experiments show how greatly the properties of bodies are modified by the Rontgen rays, and show that by their discovery physical science has received an agent which promises to be of the greatest service in investigating some of the properties of bodies which are now most urgently pressing for explanation.

LONDON UNIVERSITY COMMISSION BILL.

THE second reading of the London University Commission Bill was agreed to by the House of Lords on Thursday last. A full report of the debate upon the Bill was given in the *Times* of Friday, and the following abridgement of it will show the favourable feeling that exists for the appointment of the Statutory Commission to deal with the reconstitution of the University.

The Duke of Devonshire moved the second reading of this Bill. He said: As I made a short statement of the circumstances that have led to the introduction of this Bill when I moved for leave to introduce it, it will not be necessary for me to detain your lordships for any long time on this occasion. The opposition to the Bill, of which I indicated the possibility, has manifested itself in the form of a statement purporting to proceed from two bodies entitled respectively the University Defence Committee and the Gresham Commissioners' Scheme Amendment Committee. It is not stated how those committees are composed, and whilst I have no doubt that they fairly represent those parties who are known to be opposed to legislation on those lines, I do not think it will be contended that the body of opinion which is represented by those committees can be compared for a moment, either in weight or as regards scientific or educational experience, with that body of opinion which in various ways has given expression to its adoption of the principles upon which this Bill is founded. I think that in moving the second reading it may be sufficient if I say that, in my opinion, the arguments which are brought forward in this case do not establish any reason why the Bill should not be read a second time. There may be some points which are referred to in that case which may be worthy of attention in Committee, and I think that some of the statements may be eminently deserving of the attention of the Statutory Commission if it should be appointed under this Bill. Lord Davey has expressed his willingness to accept the position of chairman of this Commission if it should be appointed, and I trust that before the Bill leaves your lordships' House, or at all events as soon as there appears to be any possibility or probability of its being passed through the other House, I shall be in a position, in conjunction with him, to state the names of those gentlemen who it is proposed shall form the entire Commission. With this explanation I beg to move that this Bill be read a second time.

Lord Herschell: As I have the honour to be Chancellor of the University of London, it is only natural that I should desire to say a few words on the present occasion. The objections to the measure may, I think, be put under two heads. It is alleged that the scheme of the Commission of which Lord Cowper was chairman, even when subjected to the scrutiny and modification of the proposed Statutory Commission, would involve two consequences—that it would lower or tend to lower the standard of the degrees, and that it would be unfair or tend to unfairness towards those students who sought to obtain a degree without having been connected with any college or collegiate instruction. The opponents to the scheme, both in the statement they have

recently made and in previous statements, always seem to me to assume that those will be the consequences. Their statement is founded upon assumption rather than any proof or evidence. If the members of the Senate shared the view of the opponents of the scheme that the consequences which they assumed would, in fact, necessarily result, I venture to say that the Senate of the University would have been found in the front rank of opposition to the scheme, and if they support the scheme it is not because they are indifferent either to the standard of education or to the interests of the external students, but because they believe that the present work of the University may be made even more valuable than it has been without any such risk as the opponents of the scheme consider must necessarily attach to it. The fear seems to be that the scheme which has been proposed would give the teachers in London schools and colleges more power in the direction of examinations and course of study than they possess at present, and that a likely consequence of their obtaining that greater power would be a lowering of the standard of education at the University. But here again we are not without experience. First let me say that the high standard that has been maintained has been largely due to the examiners. Who have the examiners been who have thus maintained the standard of the examinations? They have very largely consisted of the teachers of the London schools and colleges. That is a matter of experience which is of much more value than any mere assumption. There is a very large consensus of opinion amongst these teachers, who have had much greater experience than can be claimed by any body of graduates, in favour of the proposed changes. The Royal Commission have impartially considered the views of those who are in favour of the scheme and of those who are opposed to it, and they have arrived at the conclusion that the scheme is one which is likely to be of public advantage and will be detrimental to no one. I only desire further to remark that I think that the scheme of the Cowper Commission, although on the whole an admirable one, is susceptible of improvement in its details, leaving its general principles untouched. The very object of appointing the Statutory Commission is to carry out those recommendations, and that the details should be looked at by a body of able men, and that the weight and force of the objections raised to those details should be fully considered and, where necessary, modified. I know that some of the opponents of the present scheme desire to create another University in London alongside of the University of London. That is a question that has been considered by men of great weight and authority, who have very largely pronounced against the proposal. The House of Commons has emphatically pronounced against it, and I believe that the country has also pronounced against it in an equally emphatic manner. Under these circumstances, I believe the best hope for the solution of this question and for the increase, even, of the valuable work which the University of London has done, lies in the direction proposed by the noble Duke.

Earl Cowper, speaking as chairman of the Commission that considered this question, said that when the work of that body first began he was prepossessed in favour of the Gresham scheme, because he thought everybody would admit that, if there was to be a second University, that scheme would have been at least as good as any other which could have been devised. But he found that the large majority of his fellow Commissioners were of a contrary opinion, and as the evidence proceeded he became more and more convinced that the great bulk of opinion throughout the country, and more particularly in the metropolis, was not in favour of a second University, but in favour of one. He could not help feeling pretty sure that everybody who went through the voluminous mass of evidence would gradually come to the same conclusion as that at which he had arrived.

Lord Playfair said that he introduced a Bill last year for the purpose of converting the present London University into a teaching University, and as the noble Duke had accepted the Bill he would strongly urge that the Government should take the matter up in earnest, considering the enormous amount of support which they now had in regard to the scheme. This scheme had been under the consideration of educationists for a whole generation. Three times the Convocation of the existing London University had met and discussed the principles of this Bill, and by increasing and finally by an overwhelming majority had pronounced in their favour. The minority of the Convocation, and individual graduates in the country, refused to accept their defeat, and were still alarmed at the proposed changes in the constitution of the present University. At the basis of their opposition was the fear that the new University might lower the value of degrees, and thus lessen the honour in which the existing graduates were now held. This fear did not seem to be shared to any extent by graduates who had the highest degrees. They had never had it explained why an organised teaching University should think it to their interest to lower the value of the degrees. One would say that their interest was to keep up the degrees to the highest value, and he thought the graduates, when they considered the question, would gradually come to this view. London was the only large town—he would not say the only capital—which did not possess an organised teaching University. It was a most melancholy fact—a fact that was a disgrace to the metropolis, that, although the towns of great population possessed organised teaching Universities, the London University did not yet do so. It was impossible that the London University, with its present powers and its present charters, could constitute a teaching University in accord with the science of the time. Teaching by verbalism was more and more going out in science. Lecturers were of far less importance than experimental work in laboratories. For this purpose well-equipped colleges were absolutely necessary, and the object of the University would be to raise itself continually up to the level of science. The object of this scheme, for which educationists had been agitating for so many years, was to produce this result. The Bill would provide a system of education capable of raising itself continually to the heightening and advancing state of knowledge. It did not provide the means, however; but if they erected an organised University of which Londoners and the people of this country would be proud, he was perfectly sure that the funds would not be lacking. He would give one instance of why they should have that confidence. The late Royal Commission appointed a small committee, consisting of Prof. Burdon-Sanderson and himself, to consider the scientific part of the report; and they recommended the foundation of research laboratories for chemistry and physics, independent of the existing colleges, but open to any of the graduates who showed the power of advancing the boundaries of science by original researches. Their recommendation was adopted after some hesitation on the part of their colleagues, because they thought they were asking too much, for no funds were in view for building and equipping such laboratories or for maintaining them when equipped. The generosity of one scientific manufacturer —Mr. Mond—had already founded these laboratories, which two years ago looked so hopeless of accomplishment. Like results would follow in regard to other recommendations of the Commission. He would like to point out how important it was that a large community like that should put itself into the position of having organised University teaching as other places had. They were doing nothing in this country at the present moment compared with what was being done in other countries for the promotion of higher University education. After the Franco-German war the French Institute had a most interesting discussion upon the question, "Why did our late crisis produce no great people in this country?" and the universal feeling in the Institute was that France had not sufficiently attended to her higher University education. Renan, in summing up the whole debate, said:—"It is German science that won the day at Sadowa and Sedan. The German national spirit is a product of the German Universities, and the German Fatherland is a product of that spirit." Inspired by these views France, since the war, had spent nearly 100 millions of francs in equipping her higher colleges, so that they might suffice for modern scientific requirements; and it now spent annually about as much as Germany in higher education. Germany had not stood still. When she acquired Strasburg as a result of the war, she spent upon that small town no less than £711,000 sterling in the building of a new University and its scientific laboratories, and annually voted above £50,000 sterling for their maintenance. The future competitions of the world would not be determined by armies and navies alone, but would be mainly governed by the intellectual development of the people. In the presence of these facts, surely England could not allow its great capital to remain the only large town, either in the United Kingdom or abroad, which had no means by which organised University teaching could be given to her people.

Lord Reay said that the main purpose of the Bill was to put an end to an anomaly. London had a variety of institutions in which University education was given, but which had not the power of conferring degrees; and, on the other hand, London had an examining Board unconnected with the teaching institutions. The institutions had no crown to their edifice; the University had no foundation. The object of the scheme of the last Royal Commission was to constitute a corporate body out of these scattered fragments, and recognition was given on well-defined and broad lines to University teaching wherever it existed. The aim of the Bill was not merely educational. It had a much wider bearing. What was the cause of the increased expenditure on higher education on the continent? It was the consciousness that wealth and military power were insufficient; that higher education must provide the intellectual capital which agriculture, industry, and trade required. If we were to hold our own in this race we must use the same means. A London University would not be a mere local institution; it would eventually be an Imperial institution, profiting all classes throughout the Empire. The progress of the Bill was anxiously watched by scientific men at home as well as abroad. There was, indeed, practical unanimity among all those who had the higher interests of the country at heart that failure to give London a teaching University would be nothing less than a national disgrace.

Lord Kelvin felt that the reasons already put before their lordships for accepting the Bill were overwhelmingly strong, and he only wished to intervene because he had been mentioned as one apparently partially opposed to the provisions of the Bill. As a member of Lord Cowper's Commission he joined with Sir George Stokes and Mr. Weldon in a note expressing a preference for a separate teaching University. They had some doubts as to whether or not the functions of a teaching University could practically be added to the duties so well performed by the University of London of examining for degrees and conferring degrees upon students who had not had the benefit of instruction in colleges of universities in any part of the world. They felt the gravity of the objection that might be held to establishing another university—a rival university—beside the University of London; but when it seemed, as it did then seem to them, hopeless that the University of London could be got to undertake the duty of organising and carrying on a teaching University, they felt that the paramount object of having a teaching University in London should not on that account be given it. On his own behalf, and, he believed, on behalf of his colleagues in the note, he could say they would only have been too glad to have accepted what was now proposed by this Bill. Their doubts and hesitation had been completely set aside by what had passed. Personally he thoroughly approved of the Bill. He believed that an immense addition to the usefulness of the existing colleges in London would result from the passing of the measure. It was an anomalous state of things that there was no teaching University in London. It was not only London, but the United Kingdom, and, indeed, the whole world, that would benefit by the passing of the Bill, and therefore his desire was strong and evident, not only that the Bill might pass speedily through their lordships' House, but that it would be taken up by the House of Commons and made an Act of Parliament before the close of the present Session.

The Earl of Kimberley said that some years ago he had the honour to be President of University College, and at that time there was put forward a scheme for a separate University such as Lord Kelvin thought might be the only alternative. He then felt it would be a great misfortune if there were set up two rival universities in London, and therefore, he need hardly say, how greatly he rejoiced that they had arrived at last at a point where they seemed to have in view a conjunction of teaching and examining in the University of London. He was glad to see the noble Duke had inserted in the Bill the clause that the Commissioners were to see that provision was made for securing adequately the interests of collegiate and non-collegiate students respectively. That ought to reassure those who had placed themselves in opposition to the Bill, because an impartial Statutory Commission such as the noble Duke intended to appoint would be perfectly able to see that the statutes of the University were so framed that there would be no chance of any portion of the University work being impaired by a wrong administration of its powers.

The second reading was then agreed to.

SCIENCE FOR SECONDARY SCHOOLS.

THE Reports of the United States Commissioner of Education are known to be the most valuable publications on educational statistics and methods in the English language. The Report (1892–93), just distributed, may appear to be somewhat belated, but the contents are so instructive and exhibit so many special features, that the delay of publication may be forgiven. There are two volumes, running altogether into 2153 pages, and the amount of information contained in them is marvellous. Taking the volumes in order, we find in the first elaborate tables of statistics referring to the schools of the United States, and statistics of illiteracy for each of the States and for Europe. Then follow surveys of the educational system of Belgium, the elementary schools of Great Britain, the systems of education developed in the British Colonies, the French educational system, and a most instructive chapter on developments in the teaching of geography in Central Europe. The chapter on child-study, which practically concludes Part I. of the first volume, contains a number of interesting contributions from leading American representatives of this modern movement.

The second part of the first volume is devoted entirely to reports which were called forth on the occasion of the World's Columbian Exposition. Among these reports are detailed criticisms of American educational methods, by eminent French and German educationists. There is a survey of medical instruction in the United States, as presented in the reports of two French Commissioners appointed to make a special study of the subject, and an English version of a report on American technological schools, prepared by Prof. Riedler, of the Royal Polytechnicum at Charlottenberg. The remainder of the first volume is taken up with papers read at the Library Congress held during the Columbian Exposition, and notes on the educational exhibits.

The second volume contains the third and fourth parts of the Report. Prof. Hinsdale contributes to it a series of rare documents illustrative of American educational history, and there is incorporated in it the report of the Committee of Ten, appointed to take up the important subject of courses of instruction in secondary schools, and papers relating thereto. The chief interest for us in the volume lies in this valuable educational document.

The Committee, which was appointed by the National Council of Education, organised conferences of leading teachers of the principal subjects which enter into the programmes of secondary schools in the United States. Each of nine subjects was considered and reported upon by a conference consisting of ten members, who were selected on account of their scholarship and experience. Among the subjects discussed were four concerned with groups of sciences; viz. (1) mathematics; (2) physics, astronomy, and chemistry; (3) natural history (biology, including botany, zoology, and physiology); (4) geography (physical geography, geology, and meteorology). As a result of the conferences, a great number and variety of important changes in the scope and method of science teaching were recommended. All the conferences on scientific subjects agreed that laboratory work by the pupils was the best means of instruction, and dwelt upon the great utility of the genuine laboratory note-book; and they all declared that teachers of science in schools need at least as thorough a special training as teachers of languages or mathematics receive.

The most important recommendations made by the scientific conferences are summarised in the following pages. But all who are interested in scientific education should read the entire reports, for each is so full of suggestions and recommendations, that it is impossible to present adequate abstracts of them.

On one very important question of general policy, which affects the preparation of all school programmes, the Committee of ten, and all the conferences organised by it, were absolutely unanimous. Among the questions suggested for discussion in each conference was—"Should the subject be treated differently for pupils who are going to college, for those who are going to a scientific school, and for those who, presumably, are going to neither?" This question was answered unanimously in the negative by all the conferences; so that we have the fact that nearly one hundred eminent teachers agree that every subject which is taught at all in a secondary school should be taught in the same way and to the same extent to every pupil so long as he pursues it, no matter what the probable destination of the pupil may be, or at what point his education is to cease.

MATHEMATICS.

The form of the report of the conference on mathematics differs somewhat from that of the other reports. This report is subdivided under five headings: (1) General conclusions; (2) the teaching of arithmetic; (3) the teaching of concrete geometry; (4) the teaching of algebra; (5) the teaching of formal or demonstrative geometry.

The first general conclusion of the conference was arrived at unanimously. The conference consisted of one Government official and university professor, five professors of mathematics in as many colleges, one principal of a high school, two teachers of mathematics in endowed schools, and one proprietor of a private school for boys. The professional experience of these gentlemen and their several fields of work were various, and they came from widely separated parts of America; yet they were unanimously of opinion "that a radical change in the teaching of arithmetic was necessary." They recommend "that the course in arithmetic be at once abridged and enriched; abridged by omitting entirely those subjects which perplex and exhaust the pupil without affording any really valuable mental discipline, and enriched by a greater number of exercises in simple calculation, and in the solution of concrete problems." They specify in detail the subjects which they think should be curtailed or entirely omitted, and they give in their special report on the teaching of arithmetic a full statement of the reasons on which their conclusion is based. They map out a course in arithmetic which, in their judgment, should begin about the age of six years, and be completed at about the thirteenth year of age.

The conference next recommend that a course of instruction in concrete geometry with numerous exercises be introduced into the grammar schools, and that this instruction should, during the earlier years, be given in connection with drawing. They recommend that the study of systematic algebra should be begun at the age of fourteen; but that, in connection with the study of arithmetic, the pupils should earlier be made familiar with algebraic expressions and symbols, including the method of solving simple equations. "The conference believe that the study of demonstrative geometry should begin at the end of the first year's study of algebra, and be carried on by the side of algebra for the next two years, occupying about two hours and a half a week." They are also of opinion "that if the introductory course in concrete geometry has been well taught, both plane and solid geometry can be mastered at this time." Most of the improvements in teaching arithmetic which the conference suggest "can be summed up under the two heads of giving the teacher a more concrete form, and paying more attention to facility and correctness in work. The concrete system should not be confined to principles, but be extended to practical applications in measuring and in physics."

In regard to the teaching of concrete geometry, the conference urge that while the student's geometrical education should begin in the kindergarten, or at the latest in the primary school, systematic instruction in concrete or experimental geometry should begin at about the age of ten for the average student, and should occupy about one school hour a week for at least three years. From the outset of this course, the pupil should be required to express himself verbally as well as by drawing and modelling. He should learn to estimate by the eye, and to measure with some degree of accuracy lengths, angular magnitudes, and areas; to make accurate plans from his own measurements and estimates; and to make models of simple geometrical solids. The whole work in concrete geometry will connect itself on the one side with the work in arithmetic, and on the other with elementary instruction in physics. With the study of arithmetic is therefore to be intimately associated the study of algebraic signs and forms, of concrete geometry, and of elementary physics. Here is a striking instance of the interlacing of subjects which seems so desirable to every one of the conferences.

Under the head of teaching algebra, the conference set forth in detail the method of familiarising the pupil with the use of algebraic language during the study of arithmetic. This part of the report also deals clearly with the question of the time required for the thorough mastery of algebra through quadratic equations. The report on the teaching of demonstrative geometry is a clear and concise statement of the best method of teaching this subject. It insists on the importance of elegance and finish in geometrical demonstration, for the reason that the discipline for which geometrical demonstration is to be chiefly prized is a discipline in complete, exact, and logical statement. If slovenliness of expression, or awkwardness of form is tolerated, this admirable discipline is lost. The conference therefore recommend an abundance of oral exercises in geometry—for which there is no proper substitute—and the rejection of all demonstrations which are not exact and formally perfect. Indeed, throughout all the teaching of mathematics the conference deem it important that great stress be laid by the teacher on accuracy of statement and elegance of form as well as on clear and rigorous reasoning. Another very important recommendation in this part of the report is to be found in the following passage: "As soon as the student has acquired the art of rigorous demonstration, his work should cease to be merely receptive. He should begin to devise constructions and demonstrations for himself. Geometry can not be mastered by reading the demonstrations of a text-book, and while there is no branch of elementary mathematics in which purely receptive work, if continued too long, may lose its interest more completely, there is also none in which independent work can be made more attractive and stimulating." These observations are entirely in accordance with the recent practice of some colleges in setting admission examination papers in geometry which demand of the candidates some capacity to solve new problems, or rather to make new application of familiar principles.

PHYSICS, CHEMISTRY, AND ASTRONOMY.

The members of this conference were urgent that the study of simple natural phenomena be introduced into elementary schools, and it was the sense of the conference that at least one period a day from the first year of the primary school should be given to such study. Apparently the conference entertained the opinion that the present teachers in elementary schools are ill prepared to teach children how to observe simple natural phenomena; for their second recommendation was that special science teachers or superintendents be appointed to instruct the teachers of elementary schools in the methods of teaching natural phenomena. The conference were clearly of opinion that from the beginning this study should be pursued by the pupil chiefly, though not exclusively, by means of experiments and by practice in the use of simple instruments for making physical measurements. The report dwells repeatedly on the importance of the study of things and phenomena by direct contact. It emphasises the necessity of a large proportion of laboratory work in the study of physics and chemistry, and advocates the keeping of laboratory note-books by the pupils, and the use of such note-books as part of the test for admission to college. At the same time the report points out that laboratory work must be conjoined with the study of a text-book and with attendance at lectures or demonstrations, and that intelligent direction by a good teacher is as necessary in a laboratory as it is in the ordinary recitation or lecture room.

The great utility of the laboratory note-book is emphatically stated. To the objection that the kind of instruction described requires much time and effort on the part of the teacher, the conference reply that to give good instruction in the sciences requires of the teacher more work than to give good instruction in mathematics or the languages; and that the sooner this fact is recognised by those who have the management of schools the better for all concerned. The science teacher must regularly spend much time in collecting materials, preparing experiments, and keeping collections in order, and this indispensable labour should be allowed for in programmes and salaries. As regards the means of testing the progress of the pupils in physics and chemistry, the conference were unanimously of opinion that a laboratory examination should always be combined with an oral or written examination, neither test taken singly being sufficient. There was a difference of opinion in the conference on the question whether physics should precede chemistry, or chemistry physics. The logical order would place physics first; but all the members of the conference but one advised that chemistry be put first for practical reasons which are stated in the majority report. A sub-committee of the conference has prepared lists of experiments in physics and chemistry for the use of secondary schools, not, of course, as a prescription, but only as a suggestion, and a somewhat precise indication of the topics which the conference had in mind, and of the limits of the instruction.

NATURAL HISTORY.

The conference on natural history unanimously agreed that the study of botany and zoology ought to be introduced into the primary schools at the very beginning of the school course, and be pursued steadily, with not less than two periods a week,

throughout the whole course below the high school. In the next place, they agreed that in these early lessons in natural science no text book should be used; but that the study should constantly be associated with the study of literature, language, and drawing. It was their opinion that the study of physiology should be postponed to the later years of the high school course; but that in the high school, some branch of natural history proper should be pursued every day throughout at least one year. Like the report on physics, chemistry, and astronomy, the report on natural history emphasises the absolute necessity of laboratory work by the pupils on plants and animals, and would have careful drawing insisted on from the beginning of the instruction.

As the laboratory note-book is recommended by the conference on physics, so the conference on natural history recommends that the pupils should be made to express themselves clearly and exactly in words, or by drawings, in describing the objects which they observe; and they believe that this practice will be found a valuable aid in training the pupils in the art of expression. They agree with the conference on physics, chemistry, and astronomy that science examinations should include both a written and a laboratory test, and that the laboratory note-books of the pupils should be produced at the examination. The recommendations of this conference are therefore very similar to those of the physical conference, so far as methods go; but there are appended to the general report of the conference on natural history sub-reports which describe the proper topics, the best order of topics, and the right methods of instruction in botany for schools below the high school, and for the high school itself, and in zoology for the secondary schools. Inasmuch as both the subject-matter and the methods of instruction in natural history are much less familiar to ordinary school teachers than the matter and the methods in the languages and mathematics, the conference believed that descriptive details were necessary in order to give a clear view of the intentions of the conference. In another sub-report the conference give their reasons for recommending the postponement to the latest possible time of the study of physiology and hygiene. Like the sixth conference, the conference on natural history protest that no person should be regarded as qualified to teach natural science who has not had special training for this work—a preparation at least as thorough as that of their fellow teachers of mathematics and the languages.

GEOGRAPHY.

Considering that geography has been a subject of recognised value in elementary schools for many generations, and that a considerable portion of the whole school-time of children has long been devoted to a study called by this name, it is somewhat startling to find that the report of the conference on geography deals with more novelties than any other report, exhibits more dissatisfaction with prevailing methods, and makes, on the whole, the most revolutionary suggestions.

It is obvious, on even a cursory reading of the majority and minority reports, that geography means for all the members of this conference something entirely different from the term "geography" as generally used in school programmes. Their definition of the word makes it embrace not only a description of the surface of the earth, but also the elements of botany, zoology, astronomy, and meteorology, as well as many considerations pertaining to commerce, government, and ethnology. "The physical environment of man" expresses as well as any single phrase can the conference's conception of the principal subject which they wish to have taught. No one can read the reports without perceiving that the advanced instruction in geography which the conference conceive to be desirable and feasible in high schools cannot be given until the pupils have mastered many of the elementary facts of botany, zoology, geometry, and physics. It is noteworthy also that this conference dealt avowedly and unreservedly with the whole range of instruction in primary and secondary schools. They did not pretend to treat chiefly instruction in secondary schools, and incidentally instruction in the lower schools; but, on the contrary, grasped at once the whole problem, and described the topics, methods, and apparatus appropriate to the entire course of twelve years. They recognised that complete descriptions would be necessary in all three branches of the subject—topics, methods, and equipment; and they have given these descriptions with an amplitude and force which leave little to be desired.

More distinctly than any other conference, they recognised that they were presenting an ideal course which could not be carried into effect everywhere or immediately. Indeed, at several points they frankly state that the means of carrying out their recommendations are not at present readily accessible, and they exhibit the same anxiety which is felt by several other conferences about training teachers for the kind of work which the conference believe to be desirable. After the full and interesting descriptions of the relations and divisions of geographical science, as the conference define it, the most important sections of their report relate to the methods and means of presenting the subject in schools, and to the right order in developing it. The methods which they advocate require not only better equipped teachers, but better means of illustrating geographical facts in the schoolroom, such as charts, maps, globes, photographs, models, lantern slides, and lanterns. Like all the other conferences on scientific subjects, the ninth conference dwell on the importance of forming from the start good habits of observing correctly and stating accurately the facts observed. They also wish that the instruction in geography may be connected with the instruction in drawing, history, and English. They believe that meteorology may be taught as an observational study in the earliest years of the grammar school, the scholars being even then made familiar with the use of the thermometer, the wind vane, and the rain gauge; and that it may be carried much further in the high school years, after physics has been studied, so that the pupils may then attain a general understanding of topographical maps, of pressure and wind charts, of isothermal charts, and of such complicated subjects as weather prediction, rainfall and the distribution of rain, storms, and the seasonal variations of the atmosphere.

Their conception of physiography is a very comprehensive one. In short, they recommend a study of physical geography which would embrace in its scope the elements of half a dozen natural sciences, and would bind together in one sheaf the various gleanings which the pupils would have gathered from widely separated fields. There can be no doubt that the study would be interesting, informing, and developing, or that it would be difficult and in every sense substantial.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. G. B. MATHEWS has resigned the chair of Mathematics in the University College of North Wales, in order to be able to devote more time to study and research.

THE Executive Committee of the City and Guilds of London Institute have appointed Mr. W. E. Dalby, since 1891 University Demonstrator of Mechanism and Applied Mechanics at Cambridge, to the Professorship of Mechanics and Applied Mathematics at the Institute's Technical College, Finsbury, rendered vacant by the resignation of Prof. Perry.

Science reports the dedication, at the University of Vermont, of two new buildings—Converse Hall, a dormitory presented to the University by John H. Converse at a cost of £25,000; and a science building presented by Dr. Edward H. Williams, which, with its equipment, will cost about £40,000. The dormitory was formally presented to the University by Mr. Converse; and the science building, in the absence of Dr. Williams, by his son, Prof. Edward H. Williams, jun., of Lehigh University. On the front of the latter building are three medallions with the heads of Agassiz, Henry, and Prof. Marsh. The building contains ample accommodation for the departments of physics, chemistry, biology, electrical engineering, and metallurgy.

EARL SPENCER, in distributing the prizes on Monday to the successful pupils at Northampton School, spoke of the absolute necessity of a sound primary education for a sound secondary technical and even University education. In Japan, and in Canada, too, he found that both secondary and University education were secured to the people. The fact that England should be behind was rather curious, and he took it that a great deal of it was due to the old grammar schools and the dislike of Parliament, with these schools existing, to create a national system of secondary education in England. That more secondary and University education was required was illustrated by the fact that, while Germany, with a population of 45,000,000, had 24,000 people using her Universities, England, with 30,000,000, had only 5500 at the University.

WE learn from *Science* that a State Veterinary College has been established in New York. It is pointed out that the animal industry of the State is so important and extensive, and the relations of animal diseases so intimately interwoven with human health and well-being, that the financial and sanitary interests of the State will derive benefit from the knowledge and continued investigations of the body of experts which the College will bring together. The following have already been appointed upon the staff of the College:—Director and Professor of Veterinary Medicine, Principles and Practice, Zymotic Diseases, and State Medicine, Dr. James Law; Professor of Veterinary and Comparative Pathology and Bacteriology, Dr. V. A. Moore; Assistant Professor of Veterinary and Comparative Physiology, Materia Medica and Pharmacy, Dr. P. A. Fish; Assistant Professor of Veterinary Anatomy and Anatomical Methods, Dr. G. S. Hopkins; Professor of Microscopical Technology, Histology and Embryology, S. H. Gage; Instructor in Microscopy, Histology and Embryology, Dr. B. F. Kingsbury; Assistant in Veterinary Bacteriology, Dr. R. C. Reed.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 7.—Polarised fluorescence, by L. Sohncke. The polarisation of fluorescent light is capable of giving hints concerning the manner in which the molecules of a solid substance vibrate, and its study may form the basis of the kinetic theory of solids. Theoretically, all doubly-refracting crystals should emit polarised fluorescence. This is found to be the case. Crystals of the regular system are the only crystals which do not. The author has investigated the fluorescence of a large number of substances in confirmation of this view.—Uniformities in the spectra of solid bodies, by F. Paschen. The author investigates the distribution of energy in the spectrum of glowing iron oxide at various temperatures. Of the formula hitherto proposed for its expression, that of Weber most closely approaches the reality. It gives a nearly parabolic curve in which the energy declines on both sides from a maximum which decreases in wave-length as the temperature rises. But the want of symmetry in Weber's curve is greater than in reality. The author finds a new formula, for which he claims that it covers all the observations.—The electrical behaviour of vapours from electrified liquids, by G. Schwalbe. The author finds that the vapours rising from electrified liquids are not capable of bearing away with them any portion of the electric charge, and that Exner's theory of atmospheric electricity must therefore be abandoned.—The damping action of magnetic fields upon rotating insulators, by William Duane. Cylinders and discs of glass, sulphur, paraffin, ebonite, or quartz, oscillating between the poles of a magnet with their axes vertical and at right angles to the lines of force, experience a damping action proportional to the field intensity and to the speed of rotation. This is not due to an action on the suspending threads, nor on the viscosity of the air, nor an electrostratic effect from the current in the coils, nor to induction currents in the substance, as was proved by test experiments and calculations. It must therefore be regarded as a hitherto unobserved magnetic effect upon the insulators in question.—Effect of magnetism upon electromotive force, by A. H. Bucherer. The author finds that in solutions of neutral ferrous salts no E.M.F. exceeding 0·00001 volt can be produced by the magnetisation of one of the two iron electrodes. The E.M.F.s observed by Gross and others must be attributed to changes of concentration produced by the magnetised electrode during its solution.—On the measurement of flame temperatures by thermo-elements, especially the temperature of the Bunsen burner, by W. J. Waggener. The temperatures were determined by various thermo-couples in different parts of the flame. The highest temperature, 1700° C., was indicated in the lower portion of the external mantle. But an infinitely thin thermo-element free from conduction would probably indicate over 1770°. A wire 0·05 mm. thick still suffers from conduction, and it is actually fused in the hottest portion. A more refractory metal is required for these measurements.

Bollettino della Società Sismologica Italiana, vol. ii., 1896, No. 1.—Velocity of propagation of the Paramythia (Epirus) earthquake of the night of May 13-14, 1895, by Dr. G. Agamennone. From time-observations obtained at several places near the epicentre, at six Italian observatories and at Nicolaiew, it appears that the early tremors travelled with a velocity of 1·94 km. per sec., and the oscillations constituting the maximum phase at the rate of 1·42 km. per sec. There is no evidence of any change in the velocity with the distance from the epicentre.—Vesuvian notes (July–December 1895), by Prof. G. Mercalli.

THE last number of the *Izvestia* of the Russian Geographical Society (1895, vi.) contains a new map of Lake Onega, in which last year's measurements of the depths of the lake are embodied. The greatest depths are in its western part, where they attain from 31 to 68 fathoms. This last depth is reached in the branch by which the lake protrudes towards the north-west. A narrow valley is thus formed at its bottom, and runs north-west to south-east, in the direction of the glacial striation in that region. Another great depth is found at the top of the other fjord-like bay in the northern portion of the lake, also directed to the north-west.

WE find in the last numbers of the *Izvestia* of the East-Siberian branch of the Russian Geographical Society (1895, Nos. 1 to 5) a very good sketch of the Yakutes of Verkhoyansk, by S. Kovalik; and an interesting note on the little-known customary hunting laws of the Buryates, by M. Croll; as also a full translation, from the Mongolian, of the renowned Buddhist "Mirror of Wisdom," which gives the "History of the Kingdom of Sukawadi."—M. Prein's preliminary article on the presence of the lime-tree in the neighbourhood of Krasnoyarsk is especially interesting. It is known that that tree does not appear to the east of the Urals, and only reappears in the Amur region on the very slopes of the high central plateau. But it was lately found in the Kuznetsk Alatau mountains, and has now been discovered further to the north-east, in the neighbourhood of Krasnoyarsk.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"Magnetisation of Liquids." By John S. Townsend.

The experiments on the coefficient of magnetisation of liquids were made with a sensitive induction balance. Both circuits were commuted about sixteen times a second, so that very small inductances could be detected by the galvanometer in the secondary circuit. The principle of the method consisted in balancing the increase of the mutual induction of the primary on the secondary of a solenoid arising from the presence of a liquid in the solenoid against known small inductances. Thus, if the sum of the inductances be reduced to zero, as shown by the galvanometer in the secondary giving no deflection, the balance will be disturbed to the extent $4\pi k\mathrm{M}$, due to the insertion of a liquid into the solenoid whose coefficient of magnetisation is k, and the galvanometer in the secondary circuit will give a deflection when the commutator revolves. An adjustable inductance is then reduced by a known amount, m, till the deflection disappears; so that we get

$$4\pi k\mathrm{M} = m \qquad \therefore k = m/4\pi\mathrm{M},$$

where m and M are quantities easily calculated.

Since the formula does not contain either the rate of the rotation of the commutator or the value of the primary current, no particular precautions are necessary to keep these quantities constant.

In all the determinations the magnetising force was varied from 1 to 9 centigram units, and in no case was there any variation in k. The densities of the salts in solution were also varied over large ranges, and showed that the coefficient of magnetisation for ferric salts in solution depended only on the quantity of iron per c.c. that was present, giving the formula

$$10^7 k = 2660\,\mathrm{W} - 7·7$$

for ferric salts, where W is the weight of iron per c.c., the quantity $-7·7$ arising from the diamagnetism of the water of solution.

A similar result was obtained for ferrous salts, the corresponding formula being

$$10^7 k = 2060\,\mathrm{W} - 7·7,$$

the temperature being 10° C.

Experiments were also performed to find the effect of heating,

and they showed a great diminution in the value of k as the temperature increased, thus letting $k = k_0 (1 - \alpha t)$ the coefficient α is the same for ferrous and ferric salts, being a function of the temperature only, its value at the lower temperatures between 5° and 25° C. being about ·0055, and at the higher temperatures between 65° and 75° C. its value is ·0035.

Paris.

Academy of Sciences, July 20.—M. A. Chatin in the chair.—Laws of uniform flow to the second approximation in circular tubes and in semicircular canals, by M. J. Boussinesq. A continuation of previous papers on the same subject.—Study of lanthanum carbide, by M. H. Moissan. This carbide, which is obtained from the oxide and carbon in the usual manner, forms a transparent yellowish crystalline mass, of the composition LaC_2. Water rapidly decomposes it at the ordinary temperature, giving acetylene, ethylene, and methane, with traces of solid and liquid hydrocarbons.—The relations between the expenditure of energy of a muscle and the amount of shortening it undergoes, by M. A. Chauveau. The method of the respiratory exchanges was used in this as in previous work on the same subject. For a given amount of external work done by the muscle, the energy used up is smaller as the muscle is nearer to its maximum length.—Report on a memoir of M. Jäderin, concerning a new method of measuring a base line, by M. Bassot. By the substitution of wires for steel tape, there is a gain in speed and also in the initial expense. The results obtained in working over well-established base lines, although agreeing amongst themselves to 1/100,000, disagree by 1/25,000 from the mean results of other methods.—Mirages and refractions observed on Lake Leman, by M. F. A. Forel.—On the photography of the sounds of the heart, by M. A. de Holowinski. The sounds are transmitted by a sensitive microphone to an optical telephone, the diaphragm of which produces Newton's rings, which are photographed.—On a new method of treating tuberculosis, by M. Fr. Crótte.—The Secretary announced the death of M. A. Kékulé von Stradonitz, Correspondent in the Section of Chemistry, on July 13.—On the summations of Gauss, by M. P. de Séguier.—On the definite quadratic forms of M. Hermite, by M. Alfred Lœwy.—On an electroscope with three gold leaves, by M. L. Benoist. The instrument described has the advantages of increased sensibility and greater certainty in the measurement of the angle of deflection.—On metallic alloys, by M. H. Gautier. Giving fusibility curves for cadmium-silver, zinc-silver, and tin-silver alloys.—On the oxygen salts of mercury, by H. Raoul Varet. A thermochemical study of the condition of some mercuric salts on solution in dilute acids.—On the action of the halogen compounds of phosphorus upon iron, nickel, and cobalt, by M. A. Granger. The phosphides Fe_4P_3, Ni_2P, and Co_2P, together with the chlorides, were obtained.—On some combinations of iodic acid with other acids, by M. Paul Chrétien. An account of the salts of molybdo-iodic, metatungsto-iodic, and phospho-iodic acids.—Action of ammonia upon the paratungstates of potash and soda, by M. L. A. Hallopeau.—Action of reducing agents upon the nitroso-compounds of osmium, by M. L. Brizard. By the reduction of $Os.(NO).OK$ in acid solution with stannous chloride an amido-compound, $Os.(NH_2).Cl_3.KCl$, is obtained.—Fermentation of uric acid by micro-organisms, by M. E. Gérard. Under certain conditions it is possible to split up uric acid in such a manner that the whole of the nitrogen appears as urea, no ammonia being formed.—Action of the chloride of sulphur upon penta-erythrite, by M. J. Bougault. A chlorhydrin and sulphurous ether are formed simultaneously.—On the determination of the freezing-point of dilute aqueous solutions, by M. A. Ponsot. A discussion of the correction recently proposed by M. Raoult.—Estimation of alcohol in the blood after direct injection into the veins, or the introduction of alcoholic vapour into the lungs, by M. N. Gréhant.—Coagulating action of the prostatic fluid upon the contents of the seminal vesicles, by MM. L. Camus and E. Gley.—The influence of lecithine upon the growth of warm-blooded animals, by M. B. Danilewsky. The injection of lecithine in small quantities causes an acceleration in growth.—On the dorsal apodeme of the Araneida, by M. Causard.—On the tubercle disease of the vine, by M. F. Lataste. The tubercles are shown to be very contagious. It is necessary to destroy by fire all infected stocks to stamp out the disease.—Direct estimation of ethyl alcohol in solutions where it is diluted in proportions between 1/500th and 1/3000th, by M. Maurice Nicloux.

Philadelphia.

Academy of Natural Sciences, June 16.—The following papers were presented for publication:—"On a collection of fishes obtained in Swatow, China, by Miss Adele M. Fielde," by Cloudesley Rutter; "On a collection of fishes made by the Rev. Jos. Seed Roberts in Kingston, Jamaica," by David Starr Jordan and Cloudesley Rutter.—Prof. Edward D. Cope continued his report on the vertebrate remains from the Port Kennedy bone-fissure. Among the Mustellidæ were five new species of the genera Lutra, Mephitis, Osmotherium, and Putorius. They were represented by at least forty individuals, and were described and named. Remains of the largest known tortoise from this section of the country were described as belonging to a new species of Clemmys. *C. insculpta* was also represented, together with a new box-tortoise belonging to the genus Toxaspis. A close ally of the black snake was also described.

TRAVELS IN EASTERN AFRICA.

Through Jungle and Desert. Travels in Eastern Africa. By William Astor Chanler, A.M. (Harv.), F.R.C.S. 8vo. Pp. xiv + 535. With 85 illustrations and 2 maps. (London: Macmillan and Co., Ltd., 1896.)

BRITISH East Africa and the adjoining parts of Africa, which are included in the spheres of influence of Germany and Italy, consist of a series of zones which run approximately parallel to the coast. Along the shore of the Indian Ocean is the low narrow coastal plain. In the interior are the high grass plains of Masailand, the dense forests and plantations of Kikuyu and Mau, and the thickly populated and well-watered basin of the Nyanza. Between these fertile zones lies a broad tract of barren, sandy, scrub-covered plains, occupied only by herds of game which follow the rains across it, or by small colonies of people who live along the banks of the rivers, or on the tracts of lava that form oases in the desert. This barren Nyika offers few attractions for man or beast, and both native traders and European explorers have hastened over it by the easiest routes to the richer countries of the Central Basin. Hence although the region of the Victoria Nyanza has been fairly well explored since first visited by Speke, the country to the north of the available routes to it has been largely left unvisited. Teleki in 1888-89 followed the great rift valley northward to Lake Rudolf; while Piggott, Peters, Hobley, and others made known the main points in the topography of the Tana Valley. But to the north of the Tana, and to the east of the Rift Valley, was a vast region of which nothing was known, except what could be gathered from the rough records of various Arab and Suahili traders, whose itineraries had been published by New and Denhardt.

"Purely in the interest of science," Mr. Chanler organised an expedition to explore this unknown land. He was fortunate in securing Teleki's able assistant, Lieut. Ludwig von Höhnel, as his companion and cartographer, and also a servant who had previously accompanied the author in a journey to Kilima Njaro. The three Europeans landed at Lamu, and formed a camp on the mainland at Mkonumbi, where they devoted three months to the organisation of the expedition. Seldom did an expedition have fairer prospects of success. Time was apparently no object, and perhaps the fact that Mr. Chanler's second name is Astor, explains why he was in the same fortunate position in regard to money. The three Europeans were men of experience in African work; they had a magnificent equipment; they had enlisted a powerful force composed of seven Somali, twelve Soudanese, and 140 Zanzibari, while Pokomo canoemen and others were engaged as required. The trade goods and armament were as suitable as the best local authorities could suggest or money buy; and their train of baggage animals and flotilla of canoes were sufficient for taking to the head of the navigable part of the Tana stores enough to last for years. In September, 1892, the march began. After many troubles, owing to the unhealthiness of the country, quarrels between the Soudanese and Somali with the Zanzibari, leading to desertions, and the death of baggage animals, the whole expedition arrived at the British East Africa Company's deserted station at Hameye. The party followed up the Tana to the confluence with the Mackenzie River. They ascended its valley, expecting that it would be the Guaso Nyiro; they found, however, that its volume gradually lessened, and that the river rises from various sources in the Jombani Mountains. Some distance further north they reached the Guaso Nyiro, which flowed to the east. They followed it till it was lost in a vast swamp known as Lake Lorian, and thus it never reaches the Tana. This was the first of the two principal discoveries made by the expedition, and it is interesting to remark that it was reported by New, from native information, as early as 1874. Disappointed at finding Lake Lorian to be only a swamp, Chanler and von Höhnel returned to the reserve camp, which had been left under Galwin at Hameye, indulging in some fighting with the natives on the way. They had some clear views of Mount Kenya, the height of which Höhnel gives as 19,650 feet; my estimate having been 19,500 feet. They started north again and moved the reserve camp to the country of the Daitcho. Chanler and von Höhnel then set out in search of a tribe known as the Randile, in order to purchase camels with which to carry their goods across the deserts to the north. They found the Randile, but could not persuade the tribe to sell camels. The account of this tribe is the most important contribution made by the expedition to African geography. For years past there have been legends of a race of "White Galla," and the traditions have come from several quarters, all pointing to the country to the east of Lake Rudolf as their home. Chanler does not refer to these legends, though they are known to all readers of Rider Haggard's novel "Allan Quartermaine." His description of the people (pp. 311-322) is the most important thing in the book, and is especially valuable as it is a simple statement of facts, every line of which shows careful observation and accurate record. The author describes the people as having a "prevailing light colour straight hair, and blue eyes," while they practise a circumcision of the navel and other rites not known among either Somali or Galla. Unfortunately there are no portraits, and no skulls were collected. The language contained many Galla words and some Masai, while the Somali could make themselves understood to the Randile. The words common to these languages, however, may easily have been adopted, and the author gives no information as to the grammar or structure of the language. Hence it seems impossible to form any idea as to the relations of this tribe; they are neither Bantu nor Nilotic, and perhaps are not even Hamitic. It seems most probable that they are the reported "White Galla," and that they entered the country from Northern Africa. Mr. Chanler's account only serves to whet our appetite for more information about this remarkable tribe. It is greatly to be hoped that the next traveller who can possibly enter into communication with it, will bring back portraits, or preferably a skull, and also get some idea of the grammatical form of the language.

Having failed in the main purpose of the visit to this tribe, Mr. Chanler returned on his tracks to the reserve camp in Daitcho, and thence marched west to join von Höhnel

at the southern end of the Loroghi mountains. The intention was to go westward to search for another tribe from which to buy transport animals. Sayer was reached, and some guides belonging to a tribe designated by a name which is no name—Wanderobbo—were secured. The country was in famine, and the Wanderobbo were starving. They begged Chanler to kill them some food, and he and von Höhnel spent some days shooting elephant, during which the author had several extraordinary escapes. He was preparing to start westward, when von Höhnel was knocked over by a rhinoceros and seriously injured. He was carried back to Daitcho, and thence sent to the coast. From this time the story of the expedition is a catalogue of disasters. All the camels had long since been dead, and most of the repeated relays of donkeys had suffered the same fate. Galwin was sent back to Ukamba to buy more of the latter. The Tana rose in flood, and for months the two halves of the expedition were separated; meanwhile the remaining donkeys were dying, and the rainy season, during which alone it was possible to cross the northern deserts, was being spent in enforced idleness. Then the Zanzibari suddenly mutinied and marched in a body to the coast. Soon after this the Soudanese, frightened by some preparations for the arrest of any Zanzibari who might be found, also bolted. The author had to destroy his stores, worth 9000 dollars, and return to the coast, which he reached at Mombasa after an absence of sixteen months.

The last pages of the volume contain the story of quarrels with the authorities at Zanzibar in regard to the treatment to be given to Chanler's deserters, who had been detained in Zanzibar. The author is very severe in his condemnations of the Zanzibar and British authorities. He declares that they suggested and instigated the mutiny, or at least gave the leader "something stronger than a hint" (p. 466); and on Mr. Chanler's return to Zanzibar, he was unable to obtain any assistance from them in securing the punishment of his men. The Prime Minister of Zanzibar, Sir Lloyd Matthews, held that the porters were justified in their desertion, and instead of punishing them, demanded from Mr. Chanler the full amount of pay due to them—a demand with which the author refused to comply. The question is an important one, but it is unnecessary to discuss it here. Mr. Chanler is naturally angry with the men whose desertion ruined his plans, and with the authorities who subsequently believed their story and took their part. Mr. Chanler admits that he has no very satisfactory theory of his men's desertion, which took him quite by surprise; or why the Zanzibar authorities should have urged his headman, Hamidi, to organise the revolt. But no one who knows General Matthews, and his readiness to help the traveller of any nationality who applies to him, will credit the charges made against him.

It is a pleasure to turn from the sad story of foiled plans, wasted chances, and angry accusations, to consider the value of Mr. Chanler's work, which represents a substantial addition to our knowledge of British East African geography. The author's text and Lieut. von Höhnel's magnificent map (which unfortunately often differ greatly in the spelling of the place-names) are contributions to the knowledge of British territories for which English naturalists and administrators must be grateful. Mr. Chanler has given us a map of an unknown region, discovered a most remarkable and interesting tribe, solved an important geographical problem, and made valuable scientific collections. He achieved these results by a generous expenditure of time and money, and at the cost of great personal hazard and hardship; and if he did not carry out the whole of the ambitious scheme at which he aimed, he displayed magnificent perseverance and courage in trying time after time, by route after route, to traverse the barren desert before him.

We cannot, however, but regret that Mr. Chanler's journey involved considerable bloodshed, and that the spirit with which he regarded this, may be gauged by his remark (p. 329), "I could not permit myself to indulge in the pleasure of an attack," although "the temptation to yield [to the entreaties of his men to seize the rich herds of a tribe with whom he had contracted the rite of blood-brotherhood] was, I must admit, next to impossible." J. W. Gregory.

APOLLONIUS OF PERGA.

Apollonius of Perga: Treatise on Conic Sections. Edited in Modern Notation, with Introductions, including an Essay on the Earlier History of the Subject, by T. L. Heath, M.A. Pp. clxx + 254. (Cambridge: at the University Press, 1896).

The assertion made in the opening lines of the preface to the book now before us, that "to the great majority of mathematicians at the present time, Apollonius is nothing more than a name and his "Conics," for all practical purposes, a book unknown," is probably well within the truth. That this should be so is a pity, because the work of the great geometer is not only valuable and interesting in itself, but affords an excellent example of the methods of Greek geometry at its best period.

Nevertheless it must be admitted that this state of things is not altogether surprising. To read through the "Conics," say in Halley's folio edition, requires not a little courage and perseverance. A modern geometrician, approaching the text for the first time, cannot fail to be struck, and is in most cases repelled, by the curious combination of crabbedness and diffuseness which it appears to present. On the one hand the nomenclature is really very concise, almost as much so, in fact, as the quasi-algebraical notation at present in vogue; on the other, there is an elaborate array of general enunciation, particular enunciation, distinction of cases, construction analysis, synthesis, and conclusion—all in strict accordance with the logical scheme which had become orthodox long before Apollonius's time. Formal demonstrations are given of propositions which we should be apt to dismiss as intuitively evident, and a preference is shown for indirect methods of proof which, in some cases, almost amounts to perversity.

Besides this, the reader who wishes to appreciate the "Conics" has to overcome a real and serious difficulty arising from the peculiar form in which the argument is presented. The Greeks elaborated the methods of geometrical proportion and the application of areas until they possessed an engine which, in capable hands, is, up to a certain point, as effective as the methods of modern

analytical geometry. In fact, a considerable part of Apollonius's treatise is coordinate geometry pure and simple; but it is expressed throughout in a strictly geometrical form. This is not without its advantages, both theoretical and practical: it avoids the thorny question of the continuity of numerical quantity, and it compels the reader to realise the meaning of every step that is taken. It is not unlikely that a well-trained Greek mathematician could follow the geometrical demonstrations as easily as the modern analyst can assimilate the corresponding algebraical proofs; it is anything but easy for one who has been brought up on the system now current to familiarise himself with the methods and points of view which prevailed in the age of the Ptolemies.

Still the labour is well worth undertaking, and Mr. Heath's edition will do much to lighten it. It may be well to state at once that the book will not relieve the serious student of the duty of consulting the original text. The editor, after performing the laborious task of literally translating the whole treatise, decided, very wisely, we think, not to publish it in that form. Instead of this, he has recast it into a form similar to that employed in most text-books on geometrical conics; he has occasionally condensed several propositions into one, made some slight rearrangements of order, and omitted, or merely given an abstract of, a certain number of propositions which are either of slight importance, or indirect proofs of converses by the usual *reductio ad absurdum*.

The result is that the English reader has before him the substance of Apollonius's great work, in a notation with which he is himself familiar, while at the same time he may, with a slight effort, read it back into the geometrical form of the original. In this sense it deserves to be called an edition, and is not a mere caricature tricked out with modern "improvements." Apart from the notation, the book really gives a trustworthy presentation of the contents and method of the original; the amount of alteration which the actual text has undergone may be estimated by the literal transcripts of Book III. Prop. 54, and Book II. Prop. 50 (one case), which will be found on pp. lxxxix–xciv of the Introduction. Some may object that the condensation is excessive; but we are inclined to think that this is not the case, when we consider the object which the editor had in view, namely to provide an edition "so entirely remodelled by the aid of accepted modern notation as to be thoroughly readable by any competent mathematician."

In this praiseworthy aim Mr. Heath has certainly succeeded, and it may be hoped that the "Conics" will now attract the attention which it undoubtedly deserves. The more the treatise is examined, the more evident become its power and comprehensiveness. Apollonius begins by considering any plane section of a circular cone, not necessarily right, and at once obtains a result equivalent to the equations of the parabola, ellipse and hyperbola in the forms

$$y^2 = px, \quad y^2 = px \pm \frac{p}{d}x^2$$

referred to a diameter and the tangent at one end of it; p being the parameter, and d the corresponding diameter. It is to be observed that, in the first instance, Apollonius speaks of *the* diameter, namely the particular one associated with the axial triangle of the cone. He then goes on to prove the existence of a conjugate diameter, and shows that any chord through the centre is bisected there: then, after a discussion of tangents, comes a very remarkable section, in which the transition is made from the original diameter and the tangent at one end of it to any other diameter and corresponding tangent. Every one is more or less aware of the fact that Apollonius practically solved the problem of drawing normals to a conic from any point in its plane; it is perhaps hardly so well known that he was acquainted with many of the focal properties of central conics, with the auxiliary circle, and with the harmonic properties of poles and polars. Oddly enough, the focus-directrix property of a conic does not appear, and was apparently unknown to Apollonius; the directrix is never used or mentioned, and the foci of a central conic are obtained by a construction equivalent to $AS.SA^1 = CB^2$. For this reason, no doubt, the focus of a parabola is not used or mentioned. But, with this one exception, almost all the principal theorems of ordinary geometrical conics are to be found in this treatise, composed more than twenty-one centuries ago.

The text of Mr. Heath's edition is preceded by a very valuable introduction, in which will be found an excellent account of the earlier history of conic sections among the Greeks, followed by an instructive essay on the characteristics and methods of Apollonius. This, with the appendix on the terminology of Greek geometry, will be of great service to those who may feel attracted towards research in the history of mathematics; a subject not interesting to many, but fascinating to the few who combine the instinct of an antiquarian with the necessary linguistic knowledge and mathematical ability.

One or two suggestions may perhaps be made in anticipation of another edition. A glossary of Greek technical terms, or at any rate an index of them, with references to the pages of the introduction where they are explained, would be a useful addition. The figures, on the whole, are clear, but some of them might be more accurately drawn; and in some of the longer and more difficult propositions it is very inconvenient to have to turn back to look at a figure on a previous page.

G. B. M.

THE HARE, FROM THE FIELD TO THE TABLE.

Fur and Feather Series.—The Hare. Edited by A. E. T. Watson. 12mo. Pp. 263. Illustrated. (London: Longmans, Green, and Co., 1896.)

FROM the first it was evident that the beautifully illustrated volumes of the "Fur and Feather Series" would appeal more to the sportsman and the *bon-vivant* than to the naturalist. That this is the case with the present issue may be inferred from the fact that out of a total of 263 pages, only a paltry sixty-two are devoted to what the author calls the natural history of the hare. As a matter of fact, it is impossible to apply the term "natural history" to the subject of more than the first forty-eight pages; the third chapter in Mr. Macpherson's

section of the work being devoted to the legislation concerning the animal in question, while the fourth bears the mysterious title of "The Hare and her Trod." From reading the text, we infer that "trod" has something to do with poaching, although of its precise signification we are still in ignorance.

In the preface to the series the editor makes it to be understood that the natural history of the animals forming the subjects of the different volumes will be treated somewhat fully. We are, however, very doubtful whether the more or less discursive gossip communicated by Mr. Macpherson is entitled to be regarded as natural history at all. There exist, it may be remembered, as models for popular monographs of any particular animal, the little volume on "The Horse," by Sir W. H. Flower, and the more pretentious work of Prof. Mivart on "The Cat"; and the author would, we think, have done well to have followed somewhat on those lines. Instead of having done this, we are not even told that the hare is a rodent, much less do we learn anything about its relatives of the same genus, and the points in which these latter differ. Beyond a few observations as to its occurrence in the different counties of Britain, and certain variations in colour and size assumed by the animal in some European countries, we are left absolutely in the dark as to the geographical range of the common hare—a subject which well merits full consideration in a work of this nature. Throughout the first chapter we find no mention of either the generic or specific names of the hare; a matter which might be passed without comment, were it not that on page 12 both scientific names of an unimportant parasite are introduced without any possible advantage. When, however, we reach page 30, we find mention for the first time of the genus *Lepus* in connection with two American species; the reader—if not a naturalist—being left to find out for himself whether the common hare is or is not a member of the same genus. What might be the aforesaid uninstructed reader's view as to the zoological position of the rabbit, we dare not hazard a guess!

Such observations as are given on the natural history of the hare, appear to relate chiefly to its breeding habits, its marvellous speed, and the depredations it commits on farm and garden crops. Although doubtless accurate enough in this way, they are very far from forming anything like a complete history of the animal, and are too discursive for our own taste, even in a popular book. Nothing in the way of new facts appears to be given, although this may well be excused.

As may be inferred from what we have written, the whole of the natural history portion of the work is from the pen of Mr. Macpherson. Several authors—among whom may be named the Hon. G. Lascelles and Mr. C. Richardson—are, however, responsible for the sporting sections; whi e the chapter on cookery has been written by Colonel K. Herbert. Whatever may be its shortcomings from a zoological point of view, the work, so far as we can judge, from the sporting aspect is in every way admirable, and it ought specially to become an invaluable companion to the country gentleman. The numerous fine illustrations make the volume excellent from an artistic point of view.

R. L.

OUR BOOK SHELF.

Grundriss einer Geschichte der Naturwissenschaften. Von Dr. Friedrich Dannemann. I. Band. Erläuterte Abschnitte aus der Werken hervorragender Naturforscher. Pp. xii + 375. (Leipzig: Wilhelm Engelmann, 1896.)

The idea upon which this book is constructed is an admirable one. By means of extracts and translations from the writings of great philosophers and investigators, a panorama of scientific history is presented in a most attractive form. Beginning with Aristotle and his Natural History, the author passes before the reader in historical succession the works and thoughts of Archimedes, Copernicus, Galileo, Gilbert, Kepler, Newton, Huyghens, Laplace, Lavoisier, Blumenbach, Cuvier, Darwin, and the host of other great thinkers and workers, who have helped to build up the edifice of scientific knowledge. To do this, Ostwald's excellent series of "Klassiker der exakten Wissenschaften" have been largely utilised. But we hasten to remark that the present volume does not merely consist of extracts and illustrations from series of reprints. A biographical note precedes the story in which each investigator tells of his work, and helpful editorialnotes are distributed throughout the book.

The work will be completed in two volumes, and we look forward with pleasure to the publication of the second one. The best text-book is the one which brings the student into close contact with the investigator, and thus creates in him a spirit of emulation. Dr. Dannemann's volume shows how this kindred feeling can be developed; therefore we welcome it as a valuable addition to scientific literature.

The Biological Problem of To-day. Preformation or Epigenesis? The Basis of a Theory of Organic Development. By Prof. Dr. Oscar Hertwig. Authorised translation by P. Chalmers Mitchell, M.A. Pp. xix + 148. (London: William Heinemann, 1896.)

The German edition of Dr. Hertwig's discursive treatise —"Präformation oder Epigenese?"—was so fully reviewed in these columns shortly after it appeared (vol. li. p. 265, 1895), that it is unnecessary to state again the criticism contained in it of Weismann's theory of the germ-plasm and doctrine of determinants, or to go over Dr. Hertwig's own theory of the development of organisms. The fact that this translation is an authorised one, and that it bears the name of Mr. Chalmers Mitchell, is a sufficient guarantee for biologists that the arguments set forth in the original edition are faithfully reproduced. In a lucid introduction, Mr. Chalmers Mitchell states the positions taken by Weismann and Hertwig, and points to the issue involved. This statement, and the glossary of technical terms, will be very helpful to readers who have but a general idea of the matters on which the argument turns. The German words "Erbgleich" and "Erbungleich," which Mr. Bourne proposed to translate isocleronomic and anisocleronomic, have been rendered by the words "doubling" and "differentiating." The word "rudiment" has been used as the equivalent of "Anlage," and most biologists will agree that it well covers the meaning of the German word.

Every one interested in the problems of heredity will be grateful for this translation of a very important treatise.

The X-Rays. By Arthur Thornton, M.A. Pp. 63. 25 illustrations. (Bradford: Percy Lund and Co., Ltd. 1896.)

This slender brochure contains a general statement of the nature of sound, light, electrical vibrations, and electrical discharges through gases, together with brief instructions for observing and photographing Röntgen phenomena, and an explanation of the theories concerning the nature of Röntgen rays. For readers desirous of obtaining an idea of the prominent features of Röntgen's discovery, the book may be recommended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Sun-spots and Faculæ.

THE following account of the nature of sun-spots and of the faculæ commonly found associated with them, explains these phenomena by refraction through the sun's atmosphere on the supposition that the centre of a spot is the centre of a high-pressure area or anticyclone.

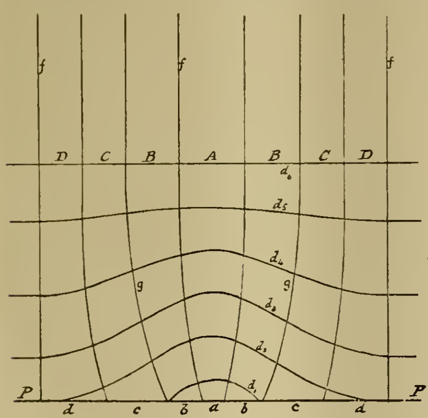
The descending central current in a solar anticyclone is caused by the exterior portion of the sun's atmosphere being at a temperature less than is consistent with convective equilibrium; consequently the whole of the descending column is colder and heavier than the atmosphere at the same level outside the area affected. The result is that the density of the atmosphere near the *base* of the column is increased, as compared with the normal density at the same level, by three different causes, viz.:—

(1) By lower temperature.

(2) By greater pressure, resulting from the upper portion of the column being colder and heavier than the normal at the same level.

(3) By additional pressure, resulting from the downward motion of the column being arrested near the photosphere; hence the pressure at the base is increased by inertia.

In the diagram annexed (a supposed section through the sun's atmosphere at a high-pressure area), the surface of the photosphere is represented by the line P P, and the successive surfaces



of equal density in the atmosphere are represented by the lines d_1, d_2, &c. These surfaces, indicating greater density in the centre of the area affected, must be convex-outwards in the centre, and concave-outwards near the margin, where they join with horizontal equal-density surfaces in the undisturbed atmosphere outside the anticyclonic action.

The area in question is seen from a distant point in the direction of E by the rays of light which emerge from the atmosphere in approximately parallel lines, represented in the diagram by the lines *f f f*. These rays before emerging must pass through the atmosphere by such courses as those represented in the diagram; that is to say, as they cross successive equal-density surfaces, moving as they do from a greater density to a less, they are refracted in a direction *less* perpendicular to these surfaces. The greatest deflection will occur about the positions of the lines *g g*, which cross the surfaces where these are most inclined to the photosphere. The areas A and B B will thus appear dark because they are seen by the light from smaller areas of photosphere, *a* and *b b*. As drawn in the figure the circular area, A, is nine times the area *a*, and consequently its mean brightness would be only one-ninth normal brightness; and the annular area, B B, being three times the area *b b*, would appear one-third normal brightness.

Beyond the greatest deflection lines, *g g*, the annular area on the photosphere is of greater width and less diameter than the corresponding annular area at the surface of the atmosphere. As drawn in the figure, the annular area, C C, is equal to *c c*, and would appear of normal brightness; while the area, D D, is about two-thirds of *d d*, and would appear of one and a half times normal brightness. In this region one or more faculæ would be seen surrounding the spot; one only if the concave-outwards curves of the equal-density surfaces were superposed one on another, as in the diagram; while if some series of such curves extended beyond others, more faculæ would be seen.

The occurrence of "eruptive prominences" near (but not at) the position where a spot has disappeared on the margin of the sun, is accordant with an anticyclonic motion round the spot; for this motion premises a rising-up of the lower atmosphere in the outer portion of the area affected. So also the greater width of the absorption-lines of the solar spectrum over a sun-spot, indicating that the absorbing atmosphere is there of greater pressure, is accordant with the theory here advanced.

It should be noticed that the brightness of the surrounding faculæ according to this theory arises simply from the light in which the spot is deficient.

JAMES RENTON.

Observatorio Nacional, Cordoba, Argentine Republic.

Sailing Flight.

IN NATURE, May 14, p. 25, you have a notice of two works on flight of birds, and I am rather surprised to see that the theory of upward currents in the air is still adhered to.

In NATURE, November 4, 1880, I laid a few remarks before you on this subject, aided by a little diagram, and on re-perusing this can see little to add to them, and nothing to alter.

It seems to me that upward currents of air, to account for sailing flight of birds, is, firstly, quite needless; secondly, they cannot be seen or proved to exist; and thirdly, the entire absence of such currents can be (at least out here) optically demonstrated.

As stated in my note (November 4, 1880), above referred to, we have two steady winds out here, from N.E. and S.W.; they are not at all violent or gusty—indeed, if directed vertically they could not possibly lift and sustain a 20 lb. cyrus or pelican.

But the utter absence of vertical air currents in our N.W. wind, at the very time the large birds are soaring in it, is beautifully demonstrated by the tufts of cotton, blown from the burst pods of the tall cotton trees, *Bombax malabaricum*.

For many years I have had a rather large telescope, through which to study the Noga Hill villages and cultivation, at six to thirty miles south, and for long was puzzled by the frequent appearance of small white objects, which slowly crossed the field, horizontally, at all distances and elevations, and at a speed of about ten or fifteen miles per hour. At last I found they were cotton tufts, out of which the little seed had dropped, and the beautifully steady and horizontal paths of thousands, at all distances, was often remarkable, at the time the birds were soaring. Anything approaching vertical air currents must have been at once detected, and easily visible. I have for hours watched the sailing, at 1000 and 2000 feet, of Cyrus, called here Korson (*Grus Antigoni*); Pelican, called here Dherra (*Pelicanus*); three Vultures, called here Hogren (*Gyps Inds.*), and two larger kinds; two adjutants, called here Bov Tokla (*Leptoptilus Argala* and *Nudifrons*); one jabiru, called here Telia Hareng.

Now, not one of these birds are ever seen sailing in a straight line, unless when descending. They cannot rise, or even sustain themselves, without flapping the wings, unless in a breeze, and when moving in a curve or spiral.

For the first 200 or 300 feet, in rising, they flap vigorously, and when well above the surface eddies, begin sailing in spirals, rising ten and twenty feet at each lap, wings held rigidly extended, and the tail alone seen to move now and then, and so on to 1000, 2000 and 3000 feet.

The primary feathers are each *widely* separated, thus giving a superposed aëroplane, at the wing extremities—

the body, say 20 lb., suspended between and below them. Each primary feather, which naturally is bent thus—

is strongly bent up, by a force equal to 8 oz., thus—

The sustaining is at the extremities, mainly. When going round *with* the breeze, the speed obviously increases, and the kite-like lift takes place when the bird turns and *meets* the same, the lift being visible, if near, and the speed also obviously slowed down.

But the drift of the rising spiral is to leeward. Varying *momentum* (of bird) in the resisting medium, must be noted; a stuffed albatross, or aëroplane, hung in a draught, will not solve the rising riddle.

The wing-plane for the moment is always part of a *cone*, outer wing highest.

When pelican travel for great distances in a straight line, their flight is at times peculiar, and they fly following each other, each bird alternating flaps or sails, thus—

the line of birds a series of waves. Our large hornbills, *Buceros bicornis*, behave in the same way.

I believe that when we look up and see a crowd of very minute specks some 5000 to 8000 feet above us (binoculars often needed), we see birds which have gone up there for coolness, and to go to *sleep*—to doze, at any rate. There is an entire absence of the mental and physical alertness and agility, which would be *constantly* needed if they depended on inequalities of wind pressure, and equally sudden, and invisible, *up gusts*, to save themselves from falling.

Herr Lilienthal is probably on the right trail. I see he desires to turn and meet the breeze; but in this movement, I fancy the upper central aëroplane—so high above the centre of gravity—will turn him over in a strong wind. In the bird's case (when turning) there is very obviously strong centripetal counter pressure, and great speed, quite sixty miles an hour I should suppose, at end of the leeward lap.

I notice that "W. J. S. L." (second paragraph, p. 301, January 30) assumes that the speed at times would be *slower* than the wind. This could only be when stopping. In the bird's case, the lifting is mainly done when it turns and meets the wind, and speed is slowed down, and the overturning is prevented, when the wings are thus, to the wind, by the great *lateral* expanse. There is none of this latter, in the centrally superposed plane machine; the bird's great lateral steadiness is structurally absent.

Soaring machines may be of two types: A, those *containing* their own power; and B, those deriving it from the surroundings only. There is no screw in the stern of the "Bov Tokla," as he wheels round and round close over me, as I sit hidden in a tuft of grass on the wide plain. Rising to windward, he circles over me at 200 feet or so, and with binoculars, or even without, I can see each feather, and hear the loud noise they make; there is never a move, except a little in the tail, yet lap by lap the bird steadily rises, and as steadily, if slowly, gets a drift to leeward.

I do not suppose the bird can soar without expenditure of energy; all I desire to point out is, that upward air currents do not lift and sustain it, also that the lifting is seen to be applied to the primary wing feathers almost entirely, and in a way which shows the lift is due to lateral translation. Tie a primary at the end of a long light stick, and on whirling it the effect is obvious.

The Position of Science at Oxford.

IT is notoriously difficult to express one's whole meaning in a condensed article. In so far as the article on the position of science at Oxford referred to the teaching of science at public schools, I see from Mr. C. I. Gardiner's letter that I have failed to express my meaning, and I must hasten to remove the impression that I intended to cast any reproach on the science masters of our public schools. I find it, indeed, difficult to understand how any one could have mistaken my meaning as much as Mr. Gardiner has done, seeing that I wrote that in every public school there are one or more science masters of tried capacity; a statement, I submit, which is entirely at variance with Mr. Gardiner's interpretation of my remarks. He makes me say that there is an absence of efficient teachers in scientific subjects; a statement which I never made, and could not make, for it would be manifestly untrue. I must admit, however, that a single sentence, "taken on the whole the science teaching at our public schools is bad," was unfortunate: I should have said that the value attached to science teaching at our public schools is altogether insufficient. Let me assure Mr. Gardiner that the last thing in the world that I should wish is that anything should be said or done to depreciate the attainments or the authority of science masters. Perhaps I may be allowed to explain. The efficiency of a machine depends firstly upon its excellence, secondly on the conditions under which it works. I do not dispute the excellence of science masters, but, speaking generally, I deplore the conditions under which they work in public schools. I stated that in public schools the inducements to learning science are very few (not nil, as Mr. Gardiner misquotes me); secondly, that it is openly discouraged; thirdly, that boys are apt to neglect studies which may safely be neglected. I adhere to each and all of these propositions. Boys, *pace* Mr. Gardiner, are as much impelled by emulation as by interest and fear (heaven forbid that fear of the cane should ever be associated with scientific teaching). Mr. Latter, in his valuable letter, throws the weight of his experience in favour of my statement: "A promising boy cannot make up by his science for deficiency in classics or mathematics . . . whereas the acute classic, however obtuse in science, is in no way hindered on his path to sixth form." No more need be said: the great inducement of emulation is wanting. If a boy neglects classics and mathematics he fails to rise in the school, is superannuated and sent away. If he neglects science, whilst working respectably at classics, he may incur formal reproof, he scarcely incurs reproach; at any rate he is in no danger of superannuation. Is it not safe, then, to neglect science? How Mr. Gardiner could have construed a harmless sentence into an attack on science teachers, I am at a loss to conceive. His conclusion is certainly not contained in the premisses, and I may be allowed to remind him that jumping to conclusions is hardly a scientific proceeding. As to the discouragement of science being no longer in existence, I can only say that Mr. Gardiner's experience is happier than mine. I trust his experience will soon become universal.

Boys do come to Oxford and to Cambridge destitute of scientific ideas. I have ample experience in Oxford, and my Cambridge friends make the same complaint. There are, of course, some few who have made science a speciality, and are well grounded, but the majority are absolutely ignorant of the alphabet of science. It is a well-known fact, and may be proved in the following way. Let it be proposed that a paper in rudimentary physics be compulsory in the "Little Go" at Cambridge, and in "Smalls" at Oxford. The proposal will be rejected by both Universities, because, it will be alleged, this minimal knowledge of science would be an insuperable barrier to the classical scholar. Moreover, it is the universal experience of those who are engaged in science teaching in the two Universities, that much of their energy is wasted in teaching the alphabet of science to those who propose to take honours in that subject. That alphabet might have been learned at school. I make no

reflection on the science masters. If the genius of the schools were something more than classical, if boys could get the same promotion for science that they do for classics, the opportunities of the science master would be increased a hundred-fold, and scientific knowledge would become the rule instead of the exception.

Throughout the article on the position of science at Oxford, I referred to public schools, only once to science masters, and that once in a complimentary sense. It should have been sufficiently clear, in spite of my unguarded sentence, that it was the spirit, the general scheme of education of our public schools, that I was attacking. Mr. Latter's letter justifies my attack. There are points in his letter which I would willingly discuss, but space forbids my entering into them now. As to the questions of Greek and the precedence of chemistry and physics over biology, there is much to be said on both sides. I will only say this: Mr. Latter is an accomplished zoologist, and his love of his subject perhaps leads him to under-estimate the intense interest which many young boys take in chemical and physical problems. After watching carefully a group of very small boys with whom I have familiar relations, I am convinced that they go after butterflies and fishes, not by preference, but because they have this opportunity of satisfying their thirst for natural knowledge, and have not the same opportunities for cultivating chemistry and physics. At any rate, if I offer to make hydrogen, or to exhibit an air-pump or an electric battery, the insects are deserted at once. Being a biologist myself, I write without prejudice in favour of the more exact sciences.

The Writer of the Article.

The Salaries of Science Demonstrators.

I fancy the incident referred to in the fable quoted by "O. J. L." (p. 271) must have happened some time ago, possibly when "O. J. L." was a tadpole himself. I am sure he would not think so lightly of our grievances if he fully realised the state of affairs in this pond of late years. At one time every tadpole who did good work had a reasonable prospect of developing into a frog on attaining a suitable age. Now there are scores of tadpoles, some of them grey-haired, who attend meetings, and croak to the best of their ability, and read papers bearing the name of some frog as joint author, but who seem fated to end their days in the tadpole stage because they cannot get sufficient food to enable them to develop into frogs.

This state of affairs is, I take it, largely attributable to the following cause. As all naturalists are aware, our ponds at certain seasons of the year are choked with frog-spawn. Under the old *régime* this spawn had to take its chance; some got dried up in the sun, and some got washed away by rain, so that only one occasional *ovum* here or there hatched. This process of survival of the fittest led to the production of a race of frogs eminently adapted to hold their own in the struggle for existence, and many of these have now acquired world-wide reputations. But Mother Carey, fearing lest any of the eggs that perished might contain the latent germs of some remarkable genius, has carefully tended this frog-spawn and hatched it in a laboratory fitted up with all the most modern incubators and other appliances, and has sometimes even nurtured it with County Council and other scholarships. So far so good. But as soon as the tadpoles are hatched, Mother Carey turns them adrift into our pond to fish for themselves, and takes no more notice of them. The result is that, where we had one tadpole formerly, there are now hundreds, struggling and starving each other out. Every morsel of food dropped into our pond (even if it be only a matter of £60 a year) leads to a terrible scramble, in which the best of us do not always come off first. I consider that we have a genuine grievance against Mother Carey on the ground that, after having devoted so much energy to hatching large numbers of tadpoles annually, she gives so little thought about finding us proper food at the time when we most need it. If we cannot all live on dry land, let us, at any rate, have a fair chance of developing our power of swimming like frogs in the water.

"An Aggrieved Tadpole."

The Date of the Glacial Period.

Mr. Davison has laid geologists under many obligations to him for his mathematical investigations of vexed or obscure questions. His suggestion in the *Geological Magazine*, that the glacial period would probably have left a long-enduring mark upon the iso-geotherms, seemed to me, as I dare say it did to other students of glacial geology, a promising one; and though a comparison, which I made of the gradients in thirty-seven cases within the glaciated area of Britain with sixteen in the unglaciated portion, failed to reveal any significant difference, still I have been disposed to ascribe the failure rather to the imperfection of the data than to any fault in the method. When, however, Mr. Davison (Nature, June 11, p. 137) extends the application of his formula to a comparison of two hemispheres, the insufficiency of the data is such as to entirely vitiate any results.

In the northern hemisphere there were available in 1885, when Prestwich wrote his memoir published by the Royal Society, 231 series of observations on the temperature of mines, tunnels and bore-holes, and it was only by what appeared to be the rather arbitrary elimination of an immense number of the records, that anything like an agreement could be obtained

What, however, is the body of evidence employed in the determination of the temperature-gradient in the southern hemisphere? One bore-hole in New South Wales! Whatever confidence we may feel in the care exercised by the observers, I cannot think that any general conclusions should be based upon this single series of observations.

There are several well-known bore-holes in the northern hemisphere in which the gradient is as far from the average given by Mr. Davison as is that of the Australian one, and, though various explanations were suggested, none was regarded as satisfactory. If Mr. Davison had referred to the Wheelton bore-hole in the 19th and 20th reports of the British Association Committee on underground temperatures, he would have found there a series of observations, made by a practised physicist, and repeated after an interval of a year under varied conditions, with practically identical results; yet here the increase of temperature was only *1° F. per 70 feet*. The St. Louis bore-hole, again, gave an average gradient of 88 feet; and though the result was regarded as erroneous, it was acknowledged that every care had been exercised, and no specific source of error could be suggested.

Taking all the circumstances into consideration, I think it will be generally conceded that, interesting as this Australian record may be, it throws no light whatever upon the vexed question of alternate glacial periods in the two hemispheres.

Percy F. Kendall.

TAXIDERMY AND MODELLING.[1]

That taxidermy has been almost an entirely neglected art is obvious to the least scientific visitor to even the best of our museums, when he regards the "deformed, distorted, and disproportioned" effigies that represent our commonest species. Every means, therefore, be it by example or precept, which will have the effect of impressing on the taxidermist the importance of his share in the exposition of natural history, and which will tend to raise what is at present little better than the knack of distending, more or less cleverly, the skins of animals with wool or shavings, to the science and art of where and why to "stuff" and reproduce, and how to pose, will be welcomed by all those who are responsible for instructing, by forms made up to simulate life, those desirous of becoming acquainted with the likeness and gait of animals which they have few or no opportunities of observing in a state of nature; and by those who turn aside to our museums to refresh their spirits with the sight of species which they have learned to love in the fields or in the sea.

The title of the work which heads this article is from the pen of Mr. Montagu Browne, the Curator of the Leicester Museum. That institution has obtained a considerable and deserved reputation for the excellence of many of its mounted groups, birds especially, as examples of the taxidermist's art, prepared by the skilled hands,

[1] "Artistic and Scientific Taxidermy and Modelling: a Manual of Instruction in the Methods of Preserving and Reproducing the Correct Form of all Natural Objects, including a chapter on the Modelling of Foliage." By Montagu Browne, F.G.S., F.Z.S., &c., Curator of the Leicester Corporation Museum and Art Gallery; author of "Practical Taxidermy," &c. With 22 full-page illustrations, and 11 in text. Pp. xii + 463. (London: Adam and Charles Black, 1896.)

we believe, of the curator himself. A work, therefore, on the subject in which he is an expert deserves attention. Taken as a whole we may at once say, that its careful perusal will well repay the practical taxidermist and modeller, for he will find the book to be a very detailed guide to the more important methods of reproducing animals and plants for exhibition purposes. Curators of museums, even though they are neither taxidermists nor modellers, will derive many excellent suggestions from its pages.

The object of the work, the author informs us, is to pave the way for the "happy combination" of qualities which he thinks the taxidermist should possess. "The future and hope of taxidermy will be," he says, "the welding of the educated artist, designer, modeller, sculptor, biologist and naturalist; and the two last are by no means synonymous terms, as some might suppose. When this happens—and there is no reason why all these attributes should not be combined in one individual—taxidermy will become an exact science relieved as painting is at present by poetic inspirations." In this opinion Mr. Browne but supports what Dr. Shufeldt, whom he quotes, has written on the subject of the taxidermist's training. Such a concatenation of qualities in one person will, we fear, remain a dream of the future. Life is not long enough for one individual to master a series of professions each arduous enough in itself for most men. Indeed, we hardly desire such a "professor" of many callings. Knowledge is never useless, but in our opinion it appears unnecessary to insist that the taxidermist of the future shall possess a scientific training in biology, or should know more anatomy and osteology than may be gained in his apprenticeship, and by very careful observation of the bodies of the animals he has to deal with; for he has to reproduce only the external surfaces as affected by various attitudes, and whichever of these he desires to reproduce he will have noted in his preliminary study of his subject. He has but to copy faithfully—neither to create, nor to use the painter's "poetic inspirations."

Following a short account of the origin and progress of taxidermy, the succeeding seven chapters (some 290 pages) deal with the skinning and setting up of vertebrates, and the preserving of invertebrates, by various methods; and also their reproduction by casting and modelling in paper, glue, &c. On these subjects Mr. Browne writes with undoubted authority and wide experience, and his instructions and descriptions are, therefore, of the greatest value. Besides the processes and methods long known and widely practised, the author claims to describe "methods of taxidermy and modelling not yet published, most of which are indeed absolutely novel, and at present confined to the Leicester Museum"; specially noteworthy among them is the mounting of the skin, which is fully described, upon a model of the body in paper, a process which, though tedious and demanding much labour and care, will probably prove to be a great improvement on that involving a "mannikin." An illustration of a model in paper of a headless tiger, on which the skin is to be fitted, is, through the courtesy of the publishers, reproduced here (Fig. 1).

FIG. 1.—Model in Paper of the Headless Body of a Tiger.

We are surprised to observe that Mr. Browne strongly decries the use of "arsenical and mercurial [corrosive sublimate] soap," as being very inefficient and too dangerous for use, and recommends in its place "a non-poisonous preservative soap" (of chalk, lime-chloride and musk) of his own devising. Notwithstanding this, we read on page 35, "the most perfect preservatives are probably those which contain [which the author's preservative does not] with alcohol a certain percentage of bichloride of mercury," and on other pages several formulæ so com-

pounded are recommended for use for skins infested with insects, for it prevents insect pests and mildew "ever appearing afterwards." Great care is always necessary in the use of poisons; but as there is no greater danger in using arsenical soap containing bichloride of mercury than an alcoholic solution of the salt, we are at loss to understand his strong denunciation of the evidently more efficient medium. The present writer has found no preservative equal to it, and has used it for thousands of skins, bird and mammal, in various regions of the globe, and cannot recollect to have lost one by moth, mite, or dermestes—except when the soap was insufficiently applied. Many of them also, after lying for years as dry skins, have been relaxed, and have proved all that could be desired. The alcoholic solution of corrosive sublimate applied to a tender skin renders it very brittle, a result entirely obviated when the salt is incorporated in the soap. Several formulæ, of which Mr. Browne claims the authorship, are given for the preservation of cartilage; but we miss any reference, either in the book itself or in the bibliography at the end, to Prof. Jeffery Parker's methods. He was one of the first, if not the first, to preserve cartilaginous fishes as "dry" specimens in museums, by very similar, if not essentially the same, processes as Mr. Browne.

Not the least valuable section of the book is the ninth chapter, describing "casting and modelling from natural foliage, flowers, fruits, algæ, fungi, &c., and their reproduction in practically indestructible materials,"—the Mintorn Art Fabric. This is quite a recent branch of the taxidermist's art—if it really belong to it—which is as important, and demands equal care an ability as the mounting of the specimen which it is to enhance. The reproduction in this material of the species of the British flora in our museums would prove a very great incentive to the study of botany, which even the best prepared herbarium can scarcely be said to do. How naturally such plants can be modelled may be seen from the second plate (Fig. 2), which we are kindly permitted to reproduce. The volume, which is dedicated to the *doyen* of museum reformers, Sir William Flower, is so beautifully printed, illustrated and bound, that we feel we cannot close our commendation of the author's part without a word of appreciation of the publishers' share in its production.

Fig. 2.—Models, in Fabric, of Sea-Aster and Flowering Rush.

PROGRESS IN STEREOCHEMISTRY.

To the stronger minds among men of science, exercised in abstract conception, and independent of such aids to the imagination as are embodied in drawings of atomic arrangements, models of molecules and even formulæ of atomic groupings, there is no doubt something almost repulsive in the representation of the molecule as a machine, a combination of mechanical powers. It is nearly forty years since the screw was suggested (by Pasteur) as a symbol of the atomic arrangement in tartaric acid, and now we find the lever introduced in such phrases as "the moment of a chain of atoms varying with its length." The wheel-and-axle has not yet been pressed into the service to explain atomic vagaries; and of the philosopher who shall venture to take this further step, the abstract thinkers of to-day will surely say, as Kolbe said of the chemist who was destined to succeed him in his professorial chair at Leipzig: "Hereby he declares that he has left the ranks of men of science, and has gone over to the camp of those philosophers of ill-omen, who are separated from the spiritualists by only a very thin *medium!*"

Yet as surely as Kolbe was succeeded by the stereochemist whose doctrines he denounced, so surely will the

vague atomic groupings of to-day be succeeded by definite systems, in which each atom will have its orbit mapped out with ever-increasing minuteness; for as long as the atomic theory endures, so long will it become more and more of a mechanical theory; and indeed it would be absolutely inconsistent, when we are perpetually striving to arrange the atoms of a molecule into groups, to give up all attempt to determine the relative positions and motions of the groups and of the atoms within them. It is as true to-day as it was when Kekulé published the statement in his "Aims and Achievements of Scientific Chemistry," that as the great present aim of physics is the elaboration of a system of molecular mechanics, so the great present aim of chemistry is the elaboration of a system of atomic mechanics, in which every reaction will be accounted for by the mass and motion of the reacting atoms. This may be deplorable; but those who think it most so, most keenly realise that it is true.

For instance, quite recently, in his plea for "Emancipation from Scientific Materialism,"[1] Prof. Ostwald wrote:—

"We read and hear with countless repetition the statement that the only intelligent explanation of the physical world is to be found in a 'Mechanics of the Atoms'; matter and motion appear as the final principles to which natural phenomena in all their variety must be referred."

With regard to physics, a similar acknowledgment is contained in the words of Duhem, uttered in 1894:—

"When the science of motion ceases to be the first in logical order of the physical sciences, and becomes only a special case of a much more general science, which embraces in its formulæ all the changes of bodies, the temptation will be less to try to reduce to the study of motion the study of all physical phenomena; it will be better understood that change of position in space is a problem no simpler than change of temperature or of any other physical property. Then we shall more easily avoid the most dangerous reef of theoretical physics—a mechanical explanation of the universe." (*Jour. de Mathématiques*, x. 207.)

Such statements as these are valuable, in that they remind us that even the most necessary of our present theories is a temporary makeshift—a crutch which indicates the weakness that it helps, and which we may hope to be able to discard.

This might be said, however, of most things that are useful; and it must be remembered that the same theory is not the best for every one. For each man that theory is the best which is the most stimulating, which best spurs him on to useful work, which urges and guides him forward into the unknown. Another theory may have more facts in its favour, but if these facts do not specially interest the worker in question, it will be of less value to him than a theory, otherwise inferior, which enables him vividly to realise, and aptly to utilise, those facts which do interest him.

Moreover, even if we admit that the atomic theory may be near the end of its existence, and that it may, and should, shortly be superseded by a more widely useful theory, it must yet be maintained that the way to hasten this consummation is to push the theory with all rapidity, and in every direction, to its extreme consequences, in the full assurance that, so far as it is incomplete, this will be the quickest way to demonstrate its deficiencies.

Now, among the consequences of the atomic theory, the consideration of the space relations of the atoms occupies the first place; it is not an extreme, but an immediate and a necessary consequence. For this reason alone, if stereochemistry did not exist, it would be necessary to invent it. But to find a *raison d'être*, stereochemistry needs no such arguments. It has justified its existence by its achievements.

The stereochemical explanation of the existence and properties of the two different substances formed when a carbon atom unites with four dissimilar groups of atoms, has long been generally admitted. As to the exact three-dimensional formulæ by which we should represent these two substances, both of which correspond to the ordinary formula $CR^1R^2R^3R^4$, differences of opinion exist; but it is certain that the formulæ must resemble those given in the figures (1 and 2), in so far as these represent three-dimensional arrangements, each unsymmetrical, but such that the two together form a symmetrical whole; in other words, each being the mirrored image of the other. And space-formulæ, in these respects similar, must be admitted for the two compounds formed by the union of a nitrogen atom with five different groups.

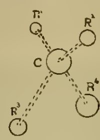

Fig. 1.

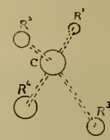

Fig. 2.

Fig. 3.

Fig. 4.

It is true that, beyond this, the services of stereochemistry are questioned by some chemists. Yet it cannot be denied that the tetrahedral grouping of the atoms combined with carbon forms a connecting link between whole groups of facts, in the most varied branches of organic chemistry, which, without it, would have been left in comparative isolation. But without entering into the necessarily complicated discussion of these developments, it may be shown, by the consideration of a single instance, that the simple original conception of the three-dimensional asymmetric grouping of dissimilar atoms about the carbon-atom to which they are attached, enables stereochemistry not merely to follow in the steps of structural chemistry, and to explain many anomalies which the latter leaves unaccounted for, but to push its investigations in advance, and to declare the space-relations prevailing in the molecules of substances as yet never analysed, and even never isolated.

The action on polarised light of a substance in solution is a test for the asymmetric grouping of the atoms in its molecules. Just as when we find a substance crystallising in two forms, such as Figs. 3 and 4, having the relation of the right and left hands, we know that these crystals will have the power of rotating the plane of polarised light to the right and to the left respectively; so when we find that a dissolved substance exerts a one-sided action on the light, we know that it possesses a one-sided molecule capable of existing in the right- and left-handed forms (Figs. 1 and 2); which, it will be observed, bear the same relation to each other as the crystal forms 3 and 4.

Further, it is known that although the two members of a pair of substances like those shown in Fig. 1 and Fig. 2, through the identity of their atoms and the equality of the distances dividing them, show no difference in their behaviour towards any ordinary substance, yet they differ entirely in their behaviour towards molecules which are themselves asymmetric. To go back to Pasteur's simile, they resemble equal screws with their threads turned in opposite directions. Both will fit the same hole equally well if it is an ordinary hole; but if it is a hollow screw, then everything will depend upon whether the thread of the hollow screw is right- or left-handed.

Conversely, if towards any substance the right- and

[1] *Science Progress*, February 1896.

left-handed molecules, $CR^1R^2R^3R^4$, act differently, we may conclude that this substance contains molecules which are themselves asymmetric. So that when we find, for example, a certain species of microscopic organism fermenting and destroying a "right-handed" sugar, but not attacking a "left-handed" sugar otherwise identical with the first, we may conclude that those molecules of the ferment which are concerned in the attack are themselves, all or some of them, of a decidedly right- or left-handed character. The line joining their atoms would itself be a spiral, the thread of a screw. And in fact we find living organisms to be largely composed of asymmetric molecules, albuminoids, which themselves exert a one-sided action on light.

It is evident, then, that there is a relation between a ferment and the substance it ferments, as between a solid screw and a hollow screw with threads which enable one to turn in the other.

And the recent researches of Fischer and Thierfelder show the relation between every turn of the two threads to be most intimate. In these experiments, twelve different species of yeast were obtained pure and free from other organisms, and fourteen different sugars were tested with each species of yeast. After eight days it was found that some of the sugars were completely fermented, some only partially, some not at all. And it was observed that the same ferment would attack sugars of widely varying composition, a sugar containing only three carbon atoms, *e.g.*, as readily as one with nine carbon atoms in its molecule. But directly it became a question of the geometrical structure of the sugar molecule the ferments showed the nicest particularity. In the case of sugars containing six carbon atoms and of exactly the same chemical composition, some would ferment readily, and others not at all.

For example, there were tested :

Dextro-glucose.	-mannose.	-galactose.	-talose.
O H C	O H C	O H C	O H C
HCOH	HOCH	HCOH	HOCH
HOCH	HOCH	HOCH	HOCH
HCOH	HCOH	HOCH	HOCH
HCOH	HCOH	HCOH	HCOH
HCOH	HCOH	HCOH	HCOH
H	H	H	H
I.	II.	III.	IV.

In each of these four molecules the atoms are the same in kind and in number. The only difference is that whereas in I. there is on one side of the molecule—say on the left, as in the formula given—only one OH group, in II. there are two OH groups on the left, in III. also two, but not the same two, and in IV. there are three. Now it is found that, with the same yeast-species, III. ferments with more difficulty than either I. or II., and the slight further change in the space-relations suffices to deprive IV. altogether of the power of fermenting. This is but one example of the way in which the yeast-cells pick and choose their food. Here, as Fischer observes, we have not simply to do with two similar substances of opposite activity—represented by screws having threads opposed throughout—but we find that of a great number of geometrical forms only a few satisfy the requirements of the yeast-cells; and these few forms are represented by screws in which the threads differ only as regards the direction of one or two of their turns. This may be illustrated by the figures below; for although it is impossible to give an exact representation of the geometrical forms of the molecules of the sugars in question, it is certain that the relations between their forms must correspond to the relations between the figures given, which are formed by a line starting from the COH group (a), joining C, OH, and H, always in the order named, and ending at the group CH_2OH (B). If the zigzag thus obtained be considered as the thread of a screw, it will be seen that in I. (Fig. 5) the thread is reversed at C^2 and again at C^3. In II. (Fig. 6), which also ferments readily, there is reversal at C^3 only, in

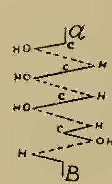

Fig. 8.

III. (Fig. 7), which ferments with difficulty, at C^2 and C^4, and in IV. (Fig. 8), which ferments not at all, at C^4 only.

These relations are shown yet more clearly in the following figures, in which the side of the OH group is represented by a broad curve, while the sharp angle is retained for the H side.

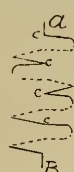

Fig. 9

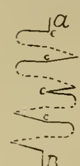

Fig. 10.

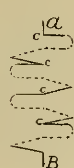

Fig. 11.

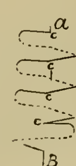

Fig. 12.

In the fermentation of all the sugars, the chief agent is, according to Fischer, proteid matter, a substance which is itself asymmetric, and which, being formed from the carbohydrates of plants, probably possesses a geometrical structure similar to that of the natural six-carbon sugars. Hence it can attack and ferment substances geometrically not far removed from these, *i.e.* from grape

sugar. The question arises, Why do not all yeasts ferment the same sugars? If the origin of the fermenting molecules is in all cases the same, has a change of environment power to alter them, provided many generations of yeast-cells are exposed to the same conditions? In order to answer this question, Fischer and Thierfelder attempted to breed a yeast which should ferment a sugar its ancestors were incapable of attacking. Starting with a yeast which could attack only dextro-glucose, they mixed this sugar with its own weight of a left-handed sugar (l-mannose), and gradually increased the proportion of the latter during three months—a time sufficient for many generations of yeast-cells to succeed one another. When the proportion of glucose was reduced to one-half per cent. the fermentation still went on, but, on reducing it to nothing, fermentation ceased altogether.

So far, then, this attempt has been a failure. In another direction, however, the research was developed with more success. The experiments described had been complicated by the presence of an unknown factor—the life of the fermenting organisms. Analogous experiments were therefore made with lifeless ferments, or enzymes, such as invertin, and emulsion, by allowing them to attack molecules differing only in the space-relations of their atoms. It was found that their power of discrimination was no less exact than that of the living cell. The difference between a glucose- and a galactose-grouping (I. and III. p. 323), which is merely a matter of H and OH changing places, is for them a difference absolutely vital. In the one case they attack the molecule, in the other they will have nothing to do with it. The explanation is similar to that given in the case of the sugars. Invertin and emulsin much resemble proteids, and no doubt possess asymmetric molecules. Their limited action on the glucosides is therefore to be accounted for by the supposition that the approximation of the molecules necessary for chemical action is possible only for molecules of similar geometrical build. To use Fischer's simile, ferment and fermented substance must fit like lock and key. For stereochemistry this image is the more valuable now that the observations have been removed from the biological to the purely chemical field of the lifeless ferments. And indeed for physiological chemistry, also, this last step is no less important, since very many of the processes which go on in the organism are effected by lifeless ferments, and must be largely influenced by the geometry of the molecule.

Nevertheless, those who already deplore the use of materialistic aids to the scientific imagination will find, in this image of the lock and key, but another count in their indictment of stereochemistry.

ARNOLD EILOART.

NOTES.

A REUTER telegram reports that the English tourist steamer *Garonne* arrived at Vadsö on August 2, and landed some of the members of the British expedition to observe the forthcoming eclipse of the sun. They proceeded at once to the south of the Varanger Fjord, where Her Majesty's cruiser *Volage* had already landed the astronomical instruments required for the observations. The steamship *Norse King* also arrived at Vadsö on Sunday with a large party of astronomers to observe the eclipse.

THE prospects of astronomers who have gone to Norway to observe the forthcoming total eclipse of the sun, are decidedly good. A telegram has just reached us stating that Mr. Norman Lockyer, assisted by officers and men of H.M.S. *Volage*, has established a camp on Kio Island, and completed the arrangements for observing the eclipse. As many as forty observers will be employed at this station in recording various characteristics of eclipse phenomena. There is every probability that fine weather will prevail on the day of the eclipse at the station selected.

CANADA is not only to be the meeting-ground of the British Association next year, but also of the British Medical Association. At the annual meeting of the latter Association, held in Carlisle last week, it was decided to accept the invitation to meet at Montreal next year, at the end of August or beginning of September. The British Association meets at Toronto on August 18, so that it will be possible for the medical members of it to attend both meetings if they wish to do so.

DR. A. BALDACCI has undertaken, during the present year, a botanical investigation of Northern Epirus, especially the district of Konitza.

THE annual meeting of the Italian Botanical Society will be held this year at Pisa, from September 10 to 17. The proceedings will commence with an evening reception, and several botanical excursions are arranged during the week.

WE regret to announce the death of Sir William Grove, at the age of eighty-five. His investigations in physical science, and especially the voltaic battery which bears his name, earned for him a wide reputation. He was elected a Fellow of the Royal Society so far back as 1840.

A METEOR of great size is reported to have fallen on July 24, at the mines of Santos Reyes in the State of Chihuahua, Mexico. A loud explosion was heard, and a mass of luminous matter was seen to fall, striking the side of a mountain, and bringing down with it in its course a large amount of rock. The meteor finally buried itself in the ground to a great depth.

AN important astronomical expedition left Chicago a few days ago for Flagstaff, Arizona, and ultimately for Mexico. Mr. Percival Lowell heads the expedition, and will make observations of Mars, assisted by Mr. A. E. Douglas. Dr. T. J. See, assisted by W. A. Coggeshall and D. A. Drew, will study double stars, and make a survey of the southern heavens. Mr. Alvan G. Clark accompanies the expedition, to put up the 24-inch telescope which has been taken.

REUTER'S correspondent at Tromsö reports that the Conway expedition has successfully accomplished the first crossing of Spitzbergen from west to east and back. Starting from their headquarters at Advent Bay, on the south side of Ice Fjord, the party ascended the Sassendal, at the head of Sassen Bay, and, branching off into a long lateral valley, climbed to the high land, which was found to be one vast glacier reaching nearly to Agardh Bay, on the Stor Fjord, or Wybe Jans Water, on the east side of the island.

THE retirement of Prof. Victor Horsley from the chair of Pathology in University College, London, has been made the occasion of presenting him with a testimonial in the form of a piece of plate and an album, as a mark of appreciation of the way in which he has advanced experimental pathology in this country. The album contains photographs of about fifty of the subscribers to the testimonial, together with a record of the work done by them, either in conjunction with Prof. Horsley or in the Brown Institution, and in the Pathological Department of University College, during the time he directed these laboratories.

AS already announced in these columns, the Committee organised by the Kazan Physico-Mathematical Society to obtain funds to found a memorial of the renowned Russian geometrician, N. J. Lobatchefsky, received the total sum of 9072 roubles (£1433) in support of that object. A circular received from Prof. Vassilief informs us that the fund has been utilised in the following manner. A capital sum of six thousand roubles has

been used to found a prize of 500 roubles to be awarded every three years for a geometrical work, and especially one on non-Euclidian geometry, printed in Russian, French, German, English, Italian, or Latin. The first prize will be awarded on November 3, 1897 (the centenary of Lobatchefsky's birth took place on November 3, 1893), and mathematicians competing for it must send in their works not later than November 3 (October 22). The sum remaining after the foundation of this prize has been devoted to the erection of a bust of Lobatchefsky, in front of Kazan University. The bust will be inaugurated on September 13 of this year, and it is hoped that as many foreign men of science as are able will be present to witness the ceremony.

A NOVEL anthropological discovery was made recently three miles from Waynesburg, in the south-western corner of Pennsylvania. A labourer, while ploughing, struck a number of stones, which proved to be graves of a character different from any heretofore discovered. Twenty vaults were found, each twenty-seven inches long, seventeen inches wide, and twelve inches deep, and each covered with a stone forty-two inches long, three inches thick, and twenty-eight inches wide at the head, thirty inches in the widest and twenty-four inches in the narrowest part. The stones were six inches below the surface of the ground. Each vault contained a skeleton of diminutive size, doubled up so as to occupy only eighteen inches of space, with the heads all in an unnatural position, and all facing the south. Under each skull was a turtle, placed as if for a pillow; and in many of the graves were skeletons of birds. The graves were arranged in the segment of a circle of almost four hundred feet in diameter. Many bone beads were found in the graves, but only one piece of metal, a small crescent-shaped copper ornament.

MR. R. H. SCOTT has sent us a copy of the report of Sir Walter Sendall, High Commissioner for Cyprus, on the succession of earthquake shocks, which we have already noted (p. 229) as occurring there at the end of June and the beginning of July. It appears that the first and most violent shock occurred about 11 p.m. on June 29, and up to the date of the report (July 4) the disturbances had continued without sign of abatement. Though most severe at Limasol, the shocks were felt from one end of the island to the other, and upwards from the sea-coast to the summit of Troodos. Mr. Mitchell, Commissioner at Limasol, reports that a shock of alarming intensity occurred at about 8.25 a.m. on July 3; the times of other movements of varying intensity felt on the same day are 12 (noon), 12.38 p.m., 2.52 p.m., 3.22 p.m. From the character of the individual shocks which, though at times very disquieting, did not produce the impression of intense and concentrated activity, it was concluded that the centre of the disturbance was at some distance from Cyprus.

THE last part (No. 12) of the first volume of the *Bollettino* of the Italian Seismological Society has reached us. The complete volume, of which we have from time to time noted the contents, includes twenty-seven papers, eight of these dealing with new instruments, four with studies of recent Italian earthquakes, and eight with the state of volcanic action in the south of the country. More than half the volume consists of notices of earthquakes registered in Italy in 1895. This section is communicated by the Central Meteorological and Geodynamic Office, and its value will be evident from the fact that it contains more than two thousand records of about 550 earthquakes. The majority of these are merely local shocks, perhaps too slight to be detected except with instrumental aid. In eighteen cases the epicentre lay outside Italy, and in three others the pulsations recorded were probably due to distant, but unknown, shocks.

THE Pigmy peoples are a source of perennial interest to anthropologists, as they undoubtedly represent a very ancient variety of the human race. The latest contribution to their osteology is a paper by Dr. R. Verneau, "On the Plurality of Ethnic Types among the Negrillos," in *L'Anthropologie* (vii. p. 153). The new material consists only of a cranium and a pelvis of a Babinga (Akka) woman from the left bank of the Middle Sangha River, about 3° S. The estimated capacity of the cranium is 1440 c.c.; this is very great for a Negrillo, being above the average of European females. Sir W. William Flower's female Akka had a capacity of only 1072, and his female Andamanese averaged 1128; 1200 c.c. is the upper limit of nannocephaly as adopted by Virchow and Kollmann. The skull is very dolichocephalic (73·2), very platyrhine (65·3), mesoseme (87·8), and has a considerable sub-nasal prognathism. These indices agree much more closely with Flower's male Akka (74·4, 63·4, 82·9) than with his female (77·9, 55·3, 82·9). The pelvis is very remarkable; so far as the form and dimensions of the brim are concerned, it is very European, but the height closely approaches that of the negress. Unfortunately there are no data from which the stature could be estimated, but the dimensions of the cranium and pelvis do not indicate pigmy dimensions; and with all due deference to Dr. Verneau, we prefer to await further evidence before accepting this as a typical dolichocephalic Negrillo.

WE have received volume iii., No. 6, and volume iv., No. 1, of that useful publication, *Indian Museum Notes*, which bids fair to rival the valuable American publications on economic entomology, upon which it is modelled. It is freely illustrated with both plates and woodcuts of destructive beetles, butterflies, moths, locusts, &c; but perhaps the most important paper in the parts before us is Mr. E. E. Green's preliminary "Catalogue of *Coccidæ* collected in Ceylon," of which he has made a special study He enumerates 72 species, 44 of which are described as new, while nearly all the remainder either represent new varieties, or species not previously recorded from Ceylon. When Mr. Kirby published his "Catalogue of the described *Hemiptera Heteroptera* and *Homoptera* of Ceylon," in the *Journal* of the Linnean Society, vol. xxiv., in 1891, he was only able to enumerate seven species of *Coccidæ* as known to occur in Ceylon. Any entomologist who cares to take up the study of a little-known group of foreign insects (or even some of the less-studied families of the smaller British insects, for that matter), may reasonably expect to be able to increase our entomological knowledge by leaps and bounds.

G. BREDDIN has published an interesting article on mimicry in *Rhynchota* in the *Zeitschrift für Naturwissenschaften*, vol. lxix., parts 1 and 2 (pp. 17–46, pl. 1). Most of the cases of insect mimicry previously recorded have been observed among *Lepidoptera*, *Coleoptera*, and *Orthoptera*; for though those presented by *Rhynchota* are equally interesting, that order is at present much neglected by entomologists. Several instances, however, were recorded by Reuter in a paper published, in 1879, in *Ofversigt af Finska Vet. Soc. Förh*, vol. xxi. This paper being in Swedish, has attracted little notice, though the late Dr. Haase made some use of it in his well-known work on mimicry. Breddin, therefore, gives a compendium of the observations of Reuter and others on mimicry in *Rhynchota*, including the results of his own investigations. He defines two forms of mimicry—protective and aggressive—the first to avoid attack, and the second to mask it, of each of which he gives numerous examples, drawn mainly, though not exclusively, from the order *Rhynchota*. The aggressive mimicry of the carnivorous masked bugs (*Reduviidæ*) and their allies is specially noticeable, and attracted the attention of many of the earliest entomologists. Those interested in mimicry will find Breddin's article

important; but it involves so much detail that a full abstract, short of a complete translation, is impracticable. It concludes with a short list of characteristic flower-frequenting beetles, by H. Hahn and P. Breddin-Magdeburg. On the coloured plate which illustrates this paper, the figures representing species of the curious Homopterous genus *Umbonia*, which resemble large thorns, are specially remarkable.

MR. W. E. NICHOLSON'S translation of the treatise in which Dr. Weismann described and discussed "New Experiments on the Seasonal Dimorphism of Lepidoptera," is concluded in the August number of the *Entomologist*. It may be remembered that the same journal published during last year a translation, by Dr. Dixey, of Dr. Standfuss's paper on the effects of artificial conditions on the development of butterflies (see NATURE, vol. liii. p. 540), and this translation, together with the one of which the publication is just completed, will doubtless be highly valued by British entomologists unacquainted with the German language. The concluding paragraph of Weismann's paper, in its English form, reads as follows: "We may now at any rate go so far as to say that the temperature *before* pupation has no influence on the colour and marking of the perfect insect. My experiments with *phlæas* already pointed to this, in so far as in this case the larvæ which hatched from Neapolitan eggs produced very different butterflies, although the pupæ only had been subjected to different temperatures, but the larvæ were all treated exactly alike. Merrifield has shown for *Ennomos autumnaria*, that the very different temperatures in which the larvæ may be reared are without influence on the colouring of the perfect insect. Therefore although, as we have recently learnt, the form of the wings of the imago is outlined very early in the larva, yet the decision as to which of two wing-determinants of an adaptively seasonally dimorphic species shall become active is, at the earliest, given at the beginning of the pupal period."

THE resources of bacteriology are seemingly inexhaustible, and its beneficent applications as varied as they are comprehensive, whilst investigations of theoretical interest are daily assuming a practical importance hardly dreamt of by their original discoverers. Little did Hellriegel, Wilfarth, and Beyerinck imagine that when they announced that certain leguminous crops are able by means of root-nodules to fix the free nitrogen of the atmosphere, and that this was accomplished by the aid of particular bacteria contained in such nodules—little did they anticipate that a few years later the great German firm of colour-manufacturers, Messrs. Meister, Lucius, and Brüning, at Höchst-am-Main, would undertake to deliver, as an article of commerce, cultivations of such bacteria under the name of *Nitragin*, wherewith to inoculate, and so supply the wants of, various leguminous crops. This is, however, what Dr. Nobbe, the distinguished follower in the footsteps of Hellriegel, has rendered by his brilliant researches an accomplished fact. Pure cultivations of nodule-organisms suitable to the growth of no less than seventeen different varieties of leguminous field crops may now be purchased from this enterprising firm. Each bottle bears a different coloured label according to the crop for which it is destined, whilst the German as well as the botanical name of the plant is also affixed. About half an acre of land may be inoculated for half-a-crown, which represents the price of a single culture bottle. The cultivations are prepared at the Höchst Works, under the direction of a former assistant to Dr. Nobbe, and the result of this latest development of practical bacteriology will be awaited with the greatest interest. Meanwhile the English Government, whilst contemplating extensive financial assistance to the agricultural interests in the country, might do well to consider whether more lasting benefit to the community might not be derived from the better endowment of science in our local colleges, and the encouragement of original research. It is the lack of this support, which in Germany is fostered so jealously, that handicaps the work, and places the worker at such a great disadvantage when compared with our more fortunate continental neighbours.

WE have received from the Deutsche Seewarte, Hamburg, a circular setting forth proposals on various questions to be raised by it at the Meteorological Conference in Paris, in September next (1) on the improvement and simplification of the exchange of weather telegrams over Europe. The introduction of the circuit-system of telegraphy, which already exists in the United States, would greatly accelerate the arrival of weather reports. Also the omission of certain details, such as the readings of wet-bulb thermometers, and maximum and minimum temperatures, not being of great importance in the preparation of weather forecasts, would lessen the cost of telegrams. (2) Uniformity of hours of observation. At present, differences of time of from one to two hours exist between the observations of different countries. So far as this country is concerned, the proposal is to take observations at 7h. a.m. instead of 8h. a.m. To carry out this recommendation, it would be necessary to open many provincial telegraph stations specially for the weather reports, as generally they do not open till 8h. a.m. Greenwich time; and in Ireland, where Dublin time is used, the offices would have to be opened still earlier. (3) Extension of the international system of meteorological publications, by means of monthly reports, and five yearly *résumés*: the investigation of the anomalies of pressure and temperature to appear only in the year-books. (4) Instruction in meteorology in schools and universities. (5) Comparison of the various sunshine recorders, and uniform instructions for the observation and exposure of the instruments. The instruments mostly in use are Jordan's photographic recorder, and the Campbell-Stokes frame and glass sphere in which the sun scorches a trace on prepared paper. (6) Maritime Meteorology. The Deutsche Seewarte will present two special papers to the Conference on the discussion and utilisation of observations made at sea.

THE Report of the Botanical Department of the State Agricultural College for Michigan is chiefly occupied by a list of the hardy plants, 1335 in number, grown in the Botanic Garden. It also contains a report of the present condition of the Herbarium (42,861 species of Flowering Plants), and some notes on Forestry.

A LARGE portion of *Botany Bulletin*, No. 13, of the Department of Agriculture, Brisbane, is occupied by a descriptive paper on the Chemistry and Economic Products of a number of Queensland Gums and Resins, by Dr. J. Lauterer. It also contains descriptions of a number of new Queensland flowering plants; additions to the Mosses, Hepaticæ, Lichens, and Fungi of the colony; and two additions to the Flora of New Guinea.

THE Helmholtz Memorial Lecture, delivered by Prof. G. F. Fitzgerald before the Chemical Society in January last, is printed in the July number of the Society's *Journal*, with a heliogravure portrait of the great investigator in honour of whom the lecture was given. It would be difficult to compose a better appreciation of a man's contributions to science than that contained in Prof. Fitzgerald's discourse.

IN another part of this issue (p. 329) will be found a notice of the fifth of an attractively produced series of reprints of old meteorological papers, edited by Dr. Hellmann. The sixth of these, "Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus," is a facsimile reprint of Hadley's paper "Concerning the Cause of the General Trade-Winds," published in the Royal Society's *Transactions* in 1735. The paper occupies little more than four pages of the publication, but Dr.

Hellmann makes up for its slenderness by means of a short biography of Hadley, and several helpful and interesting notes. The reprints are published by Messrs. A. Asher and Co.

THE *Journal of Botany* reprints some very interesting extracts from Mr. T. Kirk's presidential address to the Wellington (New Zealand) Philosophical Society, on the displacement of native by introduced species of plants. Next to man, the chief agents in this destructive work in New Zealand are sheep and rabbits, but the black rat has also had his share. "Some districts are eaten almost bare by these close feeders, little being left except the tough bases of *Poa cæspitosa* and the wiry ligneous stems of *Mühlenbeckia*, and similar plants; even the woolly leaves of some species of *Celmisia* are often closely cropped, the result being that the more delicate plants are all but extirpated over large areas." Introduced plants like *Silene anglica*, *Erigeron canadensis*, *Rumex obtusifolius* and *crispus*, *Bromus sterilis*, and *Holcus lanatus*, have almost driven out the original littoral vegetation in some districts. Even more destructive are the ravages caused by the parasites, animal and vegetable, which some of these strangers bring with them. Some idea of the extent of this invasion may be gathered from the fact that the first catalogue of naturalised plants in New Zealand, published in 1855, comprised forty-four species; while at the present time Mr. Kirk is himself acquainted with 304 species, while others put the number at 382.

WE have received the first number of vol. iii. of *Poggendorff's Biographisch-Literarisches Handwörterbuch der Exacten Wissenschaften* (J. A. Barth, Leipzig), which is to contain short biographical notices of mathematicians, astronomers, physicists, chemists, mineralogists, geologists, geographers, &c., living within the period 1858–1883. The first number extends from "d'Abancourt" to "Beilstein," and the whole volume will contain about fifteen numbers, appearing at intervals of six weeks (3*s*. each). The times preceding 1858 have already been dealt with in the first and second volumes (price 28*s*.), and any gaps which have been discovered since will be filled up in the present volume. A fourth volume is to cover the years from 1883 to 1900. The whole work will be a monument of careful compilation, and will do much to unify the world of science. The plan of the work is admirably designed. Short biographical notices are followed by a detailed enumeration of the papers and books contributed to scientific literature. Among the men of this first number, Sir G. B. Airy is *facile princeps* in the volume of his writings, as the four closely-printed columns of titles testify. There are many Arabian and other philosophers who are now seldom heard of, such as Abraham ibn Esra of Toledo, Al Marokeschi of Marocco, and Al Mahani of Khorasan, which this dictionary preserves from unmerited oblivion. Taken as a whole, the dictionary appears to be highly trustworthy, and the print and paper leave nothing to be desired.

IN the current number of the *Comptes rendus* there is an account, by M. H. Moissan, of some further experiments on the preparation of the diamond. With the view of obtaining the greatest possible pressure upon the solution of carbon in iron during solidification, the cooling with mercury or other metal was arranged in such a manner that small spheres from 5 mm. to 10 mm. in diameter were produced. These spheres gave specimens both of the black and transparent varieties of diamond, which, although very small (0·01 to 0·02 mm.), were remarkably regular and perfect in shape, agreeing exactly with the forms found in nature.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. V. Lloyd; two Amaduvade Finches (*Estrelda amandava*) from India, a Paradise Whydah Bird (*Vidua paradisea*) from West Africa, presented by Miss M. von Laer; a Raven (*Corvus corax*), British, presented by Mr. A. H. Cullingford; a Martinique Gallinule (*Ionornis martinicus*) from South America, presented by Mr. A. W. Arrowsmith; a Cape Viper (*Causus rhombeatus*), a Puff Adder (*Vipera arietans*), a Cape Bucephalus (*Bucephalus capensis*), five Hoary Snakes (*Coronella cana*), a Ring-hals Snake (*Sepedon hæmachates*), four Crossed Snakes (*Psammophis crucifer*), six Rufescent Snakes *Leptodira rufescens*), three Rough-keeled Snakes (*Dasypeltis scabra*), four Rhomb-marked Snakes (*Psammophylax rhombeatus*), a Delaland's Lizard (*Nucras delalandii*), a Defenceless Lizard (*Agama inermis*) from South Africa, presented by Mr. J. E. Matcham; four Midwife Toads (*Alytes obstetricans*), South European, presented by Prof. Gustave Gilson; a Gentoo Penguin (*Pygosceles tæniatus*) from the Falkland Islands, deposited; eight Amherst Pheasants (*Thaumalea amherstiæ*), two Peacock Pheasants (*Polyplectron chinquis*), two Himalayan Monauls (*Lophophorus impeyanus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE PLANET SATURN.—In the *Astronomische Nachrichten*, No. 3365, Prof. Barnard comments upon the accounts of various new markings on the rings and body of this planet. In company with Profs. Burnham and Hough, he carefully examined Saturn with the 18½-inch refractor at Dearborn Observatory. The planet was in a good position for seeing, being on the meridian, and during the evening several difficult double-stars were accurately measured. In spite of this, no abnormal features could be discerned, either on the globe or on the rings. The recently reported observations of new divisions, ragged edges to the crape-ring, &c., were all invisible. In fact the planet appeared very similar to what Prof. Barnard usually saw with the 36-inch Lick, although the latter, with its larger aperture, made the identification of details less difficult.

NEW NEBULOSITY IN THE PLEIADES.—W. Stratonoff, in the *Astronomische Nachrichten*, No. 3366, describes the results of recent long-exposure photographs of the Pleiades, taken with a refractor of 13 inches aperture. Three photographs are mentioned, obtained with exposures of 9h. 54m., 17h. 36m., and 25h. The first two show most of the known nebulosity, but the third shows the existence of several new features. The chief of these is a long straight streak of nebulosity extending from $\alpha = 3h.\ 40{\cdot}7m.$, $\delta = +24°\ 4'$ to $\alpha = 3h.\ 41{\cdot}9m.$, $\delta = +24°\ 4'$, roughly about 20′ north of Alcyone. The breadth of this is from 20″ to 30″; it is almost parallel to the neighbouring line of nebulosity described by M. M. Henry, and has a very similar form.

Another slight nebulosity is visible on the plate near the star 18m., in the form of several filaments lying north and south, and varying in breadth from one to three minutes of arc.

NEW VARIABLE IN HERCULES.—Mr. T. D. Anderson, of Edinburgh, gives in the *Astronomische Nachrichten*, No. 3366, a description of his observations of a 9th magnitude star, leading to the discovery of its variability. This is the star B.D. + 27°·2772, whose position for 1855·0 is given as R.A. = 17h. 4m. 58·4s., Decl. + 27° 14′·3. The star could not be found in September 1895, using a 2¼-inch refractor, but in October of the same year it was easily seen with the same instrument. Taking two neighbouring stars of magnitude 8·8 and 9·6 for comparison, he found the variation in magnitude to be from 9·2 to below 10 in about a month. In July 1896 he again found the star to be invisible as in September 1895, although the neighbouring 9·6 magnitude star was easily seen again.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE annual summer meeting of the Institution of Mechanical Engineers was held last week in Belfast, commencing on Tuesday, July 28, and concluding on Friday, July 31. There were two sittings for the reading and discussion of papers, the following being a list of those presented:—

"Flax Scutching and Flax Hackling Machinery," by John Horner, of Belfast.

"Electric Lighting in Belfast," by Victor A. H. McCowen, Electrical Engineer to the Belfast Corporation.

"Unusual Corrosion of Marine Machinery," by Hector MacColl, of Belfast.

"Rope Driving," by Abram Combe, of Belfast.

"Description of the Belfast Gas Works," by James Stelfox, Engineer and Manager.

"Description of the Alumina Factory at Larne Harbour," by James Sutherland, Manager.

"Partially immersed Screw-Propellers for Canal Boats; and the influence of Section of Waterway," by Henry Barcroft, of Newry.

The last paper was not read.

On members assembling on Tuesday, July 28, in the Examination Hall of Queen's College, Belfast, addresses of welcome were given by the Lord Mayor of Belfast, Mr. Pirrie, and by Mr. W. H. Wilson, the chairman of the Reception Committee. After this the chair was taken by the President, Mr. E. Windsor Richards, and the first paper was read.

This was Mr. Horner's contribution on flax scutching and flax hackling machinery. It was illustrated by a number of wall diagrams, without the aid of which it would be impossible to describe the intricate mechanism used in the flax industry. It is a task we will not attempt. A point of economic interest which came out in the discussion may, however, be referred to. A gentleman connected with the industry pointed out the lamentable waste that occurs owing to the unsatisfactory methods of scutching followed in Ireland. It appears that the flax-growers are always more anxious to get their money quickly for their produce than to get a full return. To scutch flax properly requires time, and also more costly machinery than is generally used in Ireland. On the continent the growers are more far-sighted, and have a larger command of capital; at any rate they have superior machines, which are more expensive at first cost, and, moreover, take a longer time in performing the operations. The foreign growers have their reward. The yield is 20 to 25 per cent. greater than with the Irish machines; and though it costs about double as much to scutch a given quantity of flax on the continental system, the yield is so much greater that a far larger profit is ultimately obtained. We gathered also from subsequent visits to the flax mills in Belfast that the continental flax is much preferred by the manufacturers, being cleaner and more easily worked. One would be inclined at first sight to attribute these facts to the conservative and shortsighted methods of the people of this country; for we are very prone to accuse ourselves of errors of this kind. It may be some satisfaction, therefore, to persons of a cynical disposition to find that the generally astute Americans are guilty of a similar fault. Mr. Dobson, of Bolton, a well-known maker of cotton-spinning machinery, told the meeting that there was an immense loss in the preparation of raw cotton, due to the very primitive ginning machinery used by the cotton-growers. It is evident that both here and in America we have something to learn from the more frugal and painstaking flax-farmers of the continent of Europe.

Mr. McCowen's paper on the electric lighting in Belfast followed. The chief feature of interest in the Belfast installation is the fact that all the prime movers are gas engines. Six of these are on the Hartley and Kerr system. They are supplied by Dick Kerr and Co., of Kilmarnock. Four are double acting, with the cylinders working tandem-wise, and having two pistons on the same rod. These engines run at a speed of 160 revolutions per minute, and indicate 120 h.p. The number of explosions per minute is 320 or 330, or 2 per revolution. The remaining two of the six gas engines are single cylinder and double acting. They also run at 160 revolutions, and indicate 60 h.p. The number of explosions per minute is 160, or one per revolution. Naturally the cyclical variation in speed of the tandem engines is very small, owing to the number of explosions, their low initial pressure, and their even distribution; the number of explosions being four to one, in comparison with the single cylinder, single acting engine; there being four complete Otto cycles in two revolutions. The method of governing is worthy of attention, as being different from that usually adopted of missing an explosion. The impulses are continuous, and the supply of gas is graduated per stroke according to the load. The quantity of air supplied to the cylinder is practically constant, the quantity of gas only being varied. This under ordinary cases would lead to a difficulty of ignition. As is well known, a poor mixture of gas and air ignites slowly; but it is said that stratification takes place in the cylinder. Taking advantage of this, gas is admitted to the cylinder later and later in the charging stroke; although even at full power a considerable quantity of air is drawn into the cylinder before gas is taken in. The full supply of air almost immediately follows the piston, while there is only a small portion of rich and explosive mixture near the ignition chest. It will be easily understood that the mechanism by which the somewhat novel operations are carried out is of an interesting nature. It was explained by the author by means of wall diagrams; but in the absence of these we can only refer our readers to the published transactions of institutions in which the diagrams will be reproduced.

These slower running engines drive the dynamos by rope-gearing, but there are two smaller engines of the high speed vertical type, manufactured by the Acme Gas Engine Company of Glasgow. They have four single-acting cylinders arranged in two lines of two in tandem, working on to opposite cranks. At full speed they run at 380 revolutions per minute. In the paper tables were given detailing the various conditions of running, quantity of gas used, &c. Without going into the details of these tables, it may be stated that the efficiency of the tandem engines does not appear to be very high, 27·4 cubic feet per electrical h.p. per hour being the best result. This, of course, could be beaten by an engine running on the Otto cycle; but we must remember that for electric lighting purposes the Otto cycle, with its one impulse in four strokes, is not well adapted unless an enormously heavy fly-wheel be used. It is the old problem that so often faces the engineer: to get efficiency in one direction something has to be sacrificed in another; and, so far as electric lighting is concerned, the engineer apparently has to choose between an increased consumption of gas, or the prospect of unsteady lights. From experience we can say that the Belfast station gives good results if we simply regard the product. But we believe that when an extension of the station is undertaken—as there is every prospect there will be shortly—steam, and not gas, will supply the motive power.

On the second day of the meeting, Wednesday, July 29, Mr. Hector MacColl's paper on the unusual corrosion of marine machinery was read. It appears that a cargo steamer was sunk on the coast of Scotland; she was loaded with "burnt ore," and was under water for a week. On examination, when the vessel was once more floated, the machinery was found to present an extraordinary appearance. All wrought-iron work was deeply and roughly corroded, and planed cast-iron work was rendered so soft as to be easily cut with a knife. As the engines of steamships are generally very little injured by submergence, even for lengthened periods of time, it was evident that there was, as the title of the paper indicated, an unusual cause for this state of affairs. This was found in the cargo. Burnt ore is the residue from the manufacture of vitriol from sulphur pyrites, and is generally found to contain about 4 per cent. of sulphate of copper, together with a little sulphate of iron, due to the sulphur not having been completely burnt out of the ore and becoming oxidised with sulphates. The sulphate of copper would be more or less completely dissolved in sea-water; and, as the latter contains a considerable quantity of chloride of sodium, this would react on the sulphate of copper, forming sulphate of sodium and chloride of copper. The sulphate of copper and chloride of copper are both soluble in water, and a solution of either or both dissolves wrought-iron and cast-iron. The chloride is more energetic in its action than the sulphate; but in time a solution of either, no matter how weak, will dissolve an atom of iron for every atom of copper present. If is satisfactory to know that the author was able, notwithstanding the great apparent damage done, to put the engines and boilers into working order again, and the ship is now doing duty on the high seas.

The next paper was perhaps the most important read at the meeting; it was Mr. Abram Combe's contribution on rope driving. As is fairly well known, Belfast is the home of rope driving as a means of conveying power from motor to machine; so far, at any rate, as mill purposes are concerned. The inventor was Mr. James Combe, of the author's firm of Combe, Barbour, and Combe, who are very large manufacturers of flax-spinning machinery. This gentleman in 1856 applied an expanding pulley with V-shaped sides to the differential motion of flax and tow roving frames, conveying the power by means of a round leather rope. He was struck by the efficiency of this gearing, and this led him to try the application of the same

means of transmission to larger power. As a result of a number of experiments he found that the following were the best ratios of diameters for ropes and pulleys :—

1¼ inch diam. rope	3 feet diam. pulley	ratio	1 to 28·8
1½ ,, ,,	4 ,, ,,	,,	1 to 32·0
1¾ ,, ,,	5 ,, ,,	,,	1 to 34·3
2 ,, ,,	6 ,, ,,	,,	1 to 36·0

In regard to power transmitted, it was found that when working under ordinary conditions the foregoing sizes of rope transmit, for each 100 revolutions per minute made by the pulley, the following :—

Rope 1¼ inch diam.	on 3 feet pulley	would give	5 I.H.P.
,, 1½ ,,	4 ,,	,,	8 ,,
,, 1¾ ,,	5 ,,	,,	11 ,,
,, 2 ,,	6 ,,	,,	15 ,,

These figures may be exceeded under more favourable circumstances. The best angle of the groove on the pulley was found to be 45°, and the best speed of rope 3300 feet per minute. Illustrations and descriptions were given of many very ingenious forms of rope driving, by which power was conveyed from a driver to a single driven pulley under conditions that would have been impossible with belts, or in any case unless complicated trains of wheel gearing had been employed. In the discussion which followed the reading of this paper, a good deal of light for the uninitiated was thrown on rope driving practice. The importance of splicing was brought to the fore, and on this depends to a large extent the durability of ropes used for conveying power. A short splice will not do at all, and even the "long splice" ordinarily made by the mariner is insufficient. For 3-inch ropes the splice has to be 12 feet long; the strands being cut and divided, so as to avoid producing what sailors call a "gouty" length; that is, one where there is an increased diameter. Three patterns of rope are used; the three strand, four strand, and the served rope. The former is far the easier to splice, the latter the most difficult. A served rope, however, has the greatest flexibility; a very prominent virtue in a driving rope, as it leads to longevity, and enables smaller pulleys to be used without ill effect. In regard to material, cotton appears to be the favourite. It is almost universally used in England; naturally so in the Lancashire district, where rope-driving practice is so largely followed. In Ireland manilla appears to be most often used. There was one speaker, who came from India, and who said that he had used coir rope with great success; this is made from the fibrous material of the husk of the cocoanut. We should have thought this substance would have been altogether too elastic for the purpose. Another speaker, Mr. McLaren, had used rope-driving for ploughing purposes, but had gone far beyond the proportions advised by the author in his table. For instance, he had used a ¾-inch rope to transmit 40 horse-power, whilst his pulleys were no more than 20 inches in diameter. This rope we understood him to say was a manilla one, but the proportions seem altogether extraordinary. We should have thought a wire rope would have been more likely to answer the purpose. The speaker, however, drew the moral that too high a factor of safety was demanded by engineers in rope driving. Later on Prof. Goodman stated that he had calculated the average factor of safety in rope driving at about 90 per cent.

One of the excursions during the meeting was made from Belfast to Larne Harbour, to visit the alumina factory there situated. A description of this factory formed the basis of Mr. Sutherland's paper. Although, as is universally known, aluminium is one of the most abundant metals found in the earth, there are not many of the compounds containing it which render themselves readily to the extraction of the metal. Bauxite is the one generally used for its production, and large deposits of this have been found in County Antrim. The analysis is as follows:—Alumina is 56 per cent., corresponding to aluminium 29·9 per cent., peroxide of iron 3 per cent., silica 12 per cent., titanic acid 3 per cent., water 26 per cent. The peroxide of iron, silica, and titanic acid have to be separated out before the extraction of the metal from the alumina is attempted; and it is the function of the Larne works to carry on these operations; the smelting of the ore being done by electrical methods at Foyers. That, however, is an operation which does not come within the scope of the paper now before us, but may form the subject later on of another contribution in the transactions of the institution.

It is the Bayer process which is used at Larne. The bauxite, as received from the mines, is first ground and sifted, after which it is taken to a calciner in order to remove the organic matter present, which would prevent the subsequent separation of the alumina from the caustic soda. The calciner is an iron tube lined with fire-brick, and caused to revolve on rollers. It is inclined at a necessary angle, the heat from the furnace passing up through the tube. As the tube inclines, the bauxite travels to the lower end, and falls out into a receptacle. The alumina is extracted from the ground bauxite by treating it with a strong solution of caustic soda under pressure. This operation is carried out in Kiers. A soluble compound of alumina and soda (aluminate of soda) is thereby formed, while the peroxide of iron, silica, and titanic acid remain as an insoluble compound. The Kiers are steam-jacketed, and have paddles mechanically actuated to agitate the mixture. The steam pressure in the jacket is carried up to 70 or 80 pounds, and the mixture is subjected to the heat corresponding to the pressure for two or three hours until decomposition is complete. The liquid product of the Kiers is then passed through filter presses, the impurities being insoluble are retained, while the liquid aluminate runs into tanks. The residue, or cakes of impurities, are afterwards washed to extract as much of the aluminate of soda as possible; and the washings are used for diluting the product of the Kiers. Centrifugal pumps are employed for this purpose. At present the red mud forming the residue is useless, and there is an opportunity for any chemist to suggest a means by which it could be utilised. Experiments are being conducted in this direction by the Company. The lyes from the presses contained in the filter tank are afterwards subjected to another filtering process, being passed through cellulose, consisting of paper-makers' pulp. About fifty pounds of cellulose is boiled with water to a thin pulp, and is run upon sieves; it soon settles down, and is then ready to receive the lyes, arresting all finely divided, insoluble particles that have escaped from the filter presses. Finally, there is another filtering process.

It is now necessary to separate the alumina from the soda. This is brought about by the addition of excess of more hydrate of alumina to the hydrate of alumina itself, and in this way about 70 per cent. of the alumina in combination with the soda separates out in thirty-six hours. The hydrate of alumina is then pumped out of the decomposing cylinders, in which the latter process has taken place, sufficient however being allowed to remain behind in the cylinder for beginning the decomposition of the next charge of liquor admitted. The hydrate of alumina pumped out is filtered through filter-presses, and the last traces of soda are removed by washing. The hydrate of alumina is then taken to the calcining furnace, where the water of hydration is driven off at a low temperature, leaving the alumina perfectly anhydrous. It will, however, take up water again readily, and to prevent this it is heated to about 2000° F., when it becomes crystalline, and not so liable to absorb moisture. The weak soda liquors which are obtained are concentrated by a triple-effect evaporator.

On the afternoon of Wednesday he members and their friends were shown these processes in operation at Larne.

The last paper read was that by Mr. Stelfox. It was not discussed, the time for the conclusion of the meeting having arrived.

The Belfast meeting was a complete success, the whole arrangements being carried out most satisfactorily. A large number of the works of Belfast were visited by members, manufacturers being most liberal in opening their establishments to members, and generally showing that hospitality for which Ireland is renowned. The summer meeting of next year is to be held in Birmingham, the city in which the Institution of Mechanical Engineers had its origin fifty years ago next year.

OLD WORLD METEOROLOGY.[1]

IN the year 1508 a book was published in Germany under the title of the "Bauern-Pracktik." This book had a wide circulation. It taught the farmer, the sailor, the merchant—all, indeed, who were interested in the weather—what would be its

[1] "Die Bauern Praktick. Neudrucke von Schriften und Karten über Meteorologie und Erdmagnetismus." Herausgegeben von Prof. Dr. G. Hellmann. (Berlin: A. Asher and Co., 1896.)

character, not only for the coming year, but in all future years. This book, with its many editions and translations, has now become very scarce, and a facsimile copy of the original has been reproduced by Prof. Hellmann, who, with the affection of the ardent bibliographer, has traced it with infinite difficulty through many libraries and into many unexpected places. To this little book, which consists of only eight or nine pages, the editor has added an introduction of some seventy, bearing the same relation to the original work that Falstaff's sack did to his bread. And just as Falstaff found his bread an unwelcome addition, so these last few pages are a hard nut to those who have not made a critical study of the German of the fifteenth century. But Prof. Hellmann's introduction gives great assistance, and by the help of it we have made out some of the rules and predictions, which appear quite as trustworthy as the prognostications that our modern weather prophets circulate, and in which no doubt they find their account.

The proper title of the book appears to be "In disem biechlein wirt gefunden der Bauren Pracktick unnd regel darauff sy das ganz iar ain auffmercken haben unnd halten." Under this title is a woodcut of a figure contemplating a crucifix, the whole surrounded by a scroll-work not badly executed. The text can be conveniently divided into three parts. The first shows how the weather, the harvest, the crops, and so forth, can be predicted from observations of the weather at Christmastide. If the weather is fair and clear on Christmas night, then there will be plenty of wine and fruit. If the weather be contrary, so will the matter fall out contrary. Then the wind is of importance. We understand the author, whoever he may be, to say that if the wind gets up at sunrise the year will be dear; but if the wind gets up at sunset, the king and the great lords will die. Like our modern prophets, the author is not afraid to indicate the course of political events. A fruitful year is foreshadowed by a west wind at midnight, but a southerly wind at midday betokens that there will be daily thunder. The author's word is "Krackhair," but whether we are justified in tracing it to "Krachen" must be decided by the student of old German. One can only regret that, with so simple a rule for his guide, one should be hindered from getting the full benefit, by his ignorance of the language in which it is written.

Then the author goes on to tell us what will happen when Christmas day falls on a Monday, Tuesday, and so on to Saturday; a very simple cycle, a little disturbed by the introduction of leap years, but nevertheless of great value to simple folk. With Christmas day on Sunday, among other things we are told that the summer will be hot and dry and fine, the autumn damp and wintry. There will be plenty of corn and wine and much honey, and if the text be correctly construed it says that "old people will die willingly"; but this seems such a contradiction to known facts, that the German must speak for itself to those who can understand it. "Die alten leüt sterben geren."

This is the kind of information that we get for each of the days of the week, and it is curious to notice the important part that honey plays in the predictions. He kills his king and his princes and his young men and his old women, but through all disasters he evidently remembers his honey, and in his partiality ranks it of equivalent importance to corn and wine.

In the next section we are told what will happen by the condition of the weather during twelve days, presumably between Christmas and Epiphany. The rules are very short, and are given without ambiguity or hedging. If the sun shines throughout Christmas day it indicates a peaceful year; if on the next day, however, money vanishes and corn becomes dear. But the third day presages something so awful that one must hope his translation is at fault. "So kriegen die bischof uñ die prelaten gern /uñ wirt irrung und den pfaffen." The spectacle of bishops, priests and deacons quarrelling is so opposed to our knowledge of their character, that some mistake has evidently glided in here, or the words do not convey the meaning which they apparently do to one only acquainted with modern German.

The book concludes with remarks of similar value on each month more or less depending upon Church festivals, and thus connecting Church observance with meteorological phenomena. This strikes one as an ingenious method of ensuring observance of the Church's calendar. If the sun shines on St. Vincent's day, we are told there will be much wine; if on St. Paul's day, a fruitful year. This last prediction recalls another of probably still older date. "Clara dies Pauli bona tempora denotat anni."

When the book passed over into a French translation a lighter note seems to have been struck, judging from the jingling rhymes by which it is recommended to the reader.

Prognostication nouvelle
Des anciens laboureurs m appelle
Je fus de Dieu transmise aux vieulx
Qui m ont approuvee en tous lieux
Et comme je diray motz a motz
Les anciens ne font pas sotz
Achepte moy quand m auras veu
Car tu ne seras point deceu
Je te donray une doctrine
Qui te vauldra d'or une mine
Et hardiment sur moy te fonde
Car je dure autant que le monde
Et si te veulz bien advertir
Que je ne te veulx point mentir.

The contents appear, however, to be but a translation of the older German work, and the subject is regarded as too sacred and important to allow any license to the playfulness of French wit, to enliven the sobriety and heaviness of the German original.

In our own country, under the title of the "Husbandman's Practice," the book seems to have enjoyed a wide popularity. No divine authority was, however, invoked, but the predictions were fathered upon the astronomers, forsooth, and this too about the time that Newton published the "Principia," and Flamsteed was at work at Greenwich. The preface runs: "The wise and cunning masters in astronomy have found, that man may see and mark the weather of the holy Christmas night, how the whole year after shall be on his working and doing, and they shall speak on this wise."

"When on the Christmas night and evening it is very fair and clear weather and is without wind and without rain, then it is token that this year will be plenty of wine and fruit." And without much alteration or addition the rigmarole is translated from the German. From a remark of Prof. Hellmann, it is to be gathered that the legend of St. Swithin as a guide to the July weather did not appear in the early German editions. It first made its appearance in the English version some time before 1668.

We find it somewhat difficult to take the work of Prof. Hellmann seriously, the predictions are so crude and ludicrous; but it is impossible to read his preface without acknowledging the care and thoroughness with which he has done his work, and the labour he has bestowed upon the subject. The book itself may not be worth a second thought, but Prof. Hellmann has made it serve the purpose of developing two lines of investigation of great interest and importance, into which, however, we cannot adequately enter. In the first place, how are we to account for the widespread hold upon the public mind that such a book had, and for so long maintained as a popular treatise? Whence comes the deep-seated love of the marvellous and superstitious, which manifested itself in many ways, and in particular is connected with the twelve days about the time of the winter solstice, when the days are at their shortest. Prof. Hellmann endeavours with some success to trace evidences in the remote past of the tendency to predict the weather from observations made on these twelve days, each day corresponding to a month in the forthcoming year. That these days have become connected with a Christian festival is to a certain extent an accident of later date.

This observation of the weather about the time of Christmas is brought out more clearly in the second inquiry, when the question of the origin of the book itself is raised, or rather on the authority on which these wise saws rest. Discarding such modern authorship as Heiny von Uri or Thomas von Filtzbach can claim, the editor shows that the book, or at least the contents of it, circulated in a traditional or MS. form long before it took its printed shape. With difficulty he has traced and compared ten MSS., dating back from 1478, all possessing common features indicating a common origin, and pointing out with some degree of plausibility to the pages of the Venerable Bede as the oldest known source. But this wish to penetrate the future, and the formation of rules for general guidance are older than this remote date, and traces of ancient customs and old predictions are to be found in all parts of the globe, wherever written records have been preserved. But there is the curious fact to be remarked, that the older MSS. show a tendency to refer the grounds for prognostication to the Calends of January rather than to the Christmas festival, and in the case of a fifteenth century MS. both are mentioned. Christmas is quite a late innovation, and the growth in importance of the great Christian festival can be traced by its gradual displacement of the older Calendar in these meteorological superstitions.

PRIZES OFFERED BY THE SOCIÉTÉ D'ENCOURAGEMENT

THE *Bulletin* of the Société d'Encouragement pour l'Industrie Nationale contains a list of the medals and prizes to be awarded in 1897 and 1898. Amongst these, the following prizes are proposed for 1897. In the Mechanical Arts: for improved methods in milling of grain (2000 francs); for a motor weighing less than 50 kilogrammes per horse-power developed for use in aerial navigation (2000 francs); for a study of the coefficients necessary for the calculations of an aërial machine (2000 francs); for a small motor suitable for domestic use (2000 francs); for improvements in machine tools (2000 francs).

In the Chemical Arts: for the utilisation of waste products (1000 francs); for a new method of preparing fuming sulphuric acid or sulphur trioxide, which shall be more economical than those at present in use (2000 francs); for a liquid which shall replace sulphuric acid in dyeing, especially of silk, without exercising the same destructive action on the fibre (1000 francs); for a scientific study of the physical and mechanical properties of glass (2000 francs); for the preparation on the large scale of a new alloy of iron possessing specially useful properties (2000 francs).

In the Economic Arts: prizes are offered for the construction of a hydro-extractor that can be worked continuously (2000 francs), and for important improvements in the manufacture of permanent magnets, with especial reference to their stability (3000 francs).

In Agriculture: for a study of alcoholic ferments (3000 francs); for the best study of the diseases of cider and the means of arresting their development (2000 francs); for the best practical means of destroying one of the insect enemies of the vine (1000 francs). There will also be awarded in 1897 a prize of 2000 francs for an economic study of an industrial centre in France, and of 1500 francs for a study of insurance against involuntary want of employment.

The more important prizes offered for 1898 include the Marquis d'Argenteuil prize of 12,000 francs for the discovery of the greatest service in developing French industry; for a publication of service to chemical or metallurgical industry (2000 francs); for an experimental study of the physical or mechanical properties of some metal or alloy in common use (2000 francs); for the invention of new methods of utilising petroleum (0 8 k. or higher) advantageously and without danger, for either manufacturing or domestic purposes (2000 francs); for the best varieties of barley for brewing (1500 francs); for the reconstitution of vineyards upon chalky soils (3000 francs); and for the best study in vine culture in France (2000 francs).

SCIENCE IN THE MAGAZINES.

GLACIALISTS making arrangements for their summer migration to Switzerland, and other geologists interested in ice-work, should read what Dr. A. R. Wallace has to say in the *Fortnightly* on "The Gorge of the Aar and its Teachings," before they set out, and they will then be able to judge for themselves the weight of the conclusions drawn. Dr. Wallace thinks the phenomena presented by the valley of the Aar afford "a fresh and very powerful argument in support of the power of the ancient glaciers both to deepen valleys and to grind out lake-basins," and his article is written to prove the correctness of this view. In the enclosed valley with its two small rock-basins in which the Hospice in the Grimsel Pass is situated, Dr. Wallace sees an example of the effects of a kind of eddy in old ice-streams flowing in nearly opposite directions. The celebrated Aarschlucht, one of the most remarkable gorges in Europe, is from 200 to 300 feet deep, and only about six feet in width. This is held to represent "the result of the action of sub-glacial torrents acting throughout the whole period during which the area was buried in ice. Thus only are we able to explain the fact of the almost uniform narrowness of the gorge from bottom to top, since during the process of its formation the rock walls would be preserved from ordinary denuding agencies, and be kept at a nearly uniform temperature." This view of the origin of the gorge is held by Prof. Bonney and by other geologists who have considered the subject, though the conclusions to which it leads differ. A number of other gorges in Switzerland are similarly explained. Accepting this interpretation, it is evident that gorges of this character ought only to be found in regions which have been recently glaciated. "In our own country," says Dr. Wallace, "we have many small gorges of this character, in Wales, the Lake District, and Scotland, that of Dungeon Gill, in Westmoreland, being an example; but more are to be found in decidedly non-glaciated areas, such as Devonshire, though narrow ravines are common enough. So in the Northern United States there are many such gorges, the Ausible Chasm in the Adirondacks, and Watkin Glen, near Seneca Lake, are well-known tourist resorts; but in the Southern States, beyond the glaciated area, there are no similar gorges, although the southern Alleghenies are loftier than farther north, and contain much grand and picturesque mountain scenery and many waterfalls and deep ravines, but these are all of the rugged and weathered type." In the mountainous region of Brazil, where there has certainly been no recent glaciation, Prof. Branner testifies that none of the characteristic sub-glacial stream channels occur. Finally, the gorges of the Aar, and others of like nature, are shown to afford evidence in favour of the theory of the glacial origin of the Swiss valley lakes. The abrupt Kirchet Hill, which extends across the valley of the Aar, is adduced by Prof. Bonney as an argument against this theory. "This would be a valid objection," says Dr. Wallace, "if the Aar glacier had continued in a straight, or nearly straight, line to Meiringen; but the influx of a large glacier stream from the north-east must have so diverted that of the Aar, that the resultant flow would have been across the lower valley, and almost along the steep face of Kirchet instead of directly across it. This would have been the case, because the glacier stream from the north-east was not only equal in size to that of the Aar valley, but had a more rapid descent, and, therefore, a quicker flow. In the last five miles the Aar valley has a fall of about 1500 feet, while the two north-eastern valleys have an average fall of about 2000 feet; and they are also much wider, which would still further facilitate rapidity of outflow."

Dr. C. M. Aikman gives in the *Contemporary* an account of the inoculation of agricultural land with pure cultures of bacteria, in the form of Nitragin, for the purpose of promoting plant-growth. A note on this advance in the science of agriculture will be found on page 326. To the same review Mr. Andrew Lang contributes a budget of records of the rite of "Passing through the Fire," beginning with the earliest accounts of this or some analogous ceremony, and concluding with the most recent authenticated contemporary examples The rite is very widely diffused, and there is a considerable amount of evidence that the fire-walking is actually practised without apparent injury. In a few villages in Turkey, on the Bulgarian frontier, a festival is held in May, and certain persons still go through the performance of treading and dancing on the red-hot embers of a pile of wood, apparently without sustaining injury. Mr. Lang appeals to men of science to take up the subject, both on account of the widely-diffused religious character of the ceremony, and in order to discover how, granting the facts, the feat is performed. A scientific observer who would go to Bulgaria on May 21 next year, and thoroughly investigate the rite there, noting the state of the fire, the condition of the feet of the ministrants before and after the performance, and photographing the scene, would obtain some definite and valuable information.

A brief mention must suffice for the remaining articles on scientific topics in the magazines received by us. The second part of an historical study, by Mr. J. F. Hewitt, entitled "How the first Priests, the long-haired Shamans, and their successors, the tonsured Barber-surgeons, measured Time," appears in the *Westminster Review*. The article contains many facts of interest as to the origin of the year in the northern and southern hemispheres. The *Century* publishes some glimpses of life in Africa, from the journals of the late Mr. E. J. Glave, who completed his remarkable journey across Africa from east to west in May 1895, and died while waiting for the departure of the homeward steamer. The *Strand Magazine* has a detailed account of the balloon, accessories, and plan of Mr. Andrée, for his aërial polar expedition. There is also a liberally illustrated account of the methods and results of Röntgen photography, by Mr. Alfred W. Porter, in the same magazine. An instructive article on "Atmospheric Pressure" is contributed to *Longman's Magazine* by Mr. H. Harries. Articles of a like character appear in *Chambers's Journal* on "The Glastonbury Lake-Dwellers," and "Work in Compressed Air."

THE REPRODUCTION OF DIFFRACTION GRATINGS.[1]

I HAVE first to apologise for the very informal character of the communication which I am about to make to the club; I have not been able to put anything down upon paper, but I thought it might be interesting to some to hear an account of experiments that have now been carried on at intervals for a considerable series of years in the reproduction—mainly the photographic reproduction—of diffraction gratings. Probably most of you know that these consist of straight lines ruled very closely, very accurately, and parallel to one another, upon a piece of glass or speculum metal. Usually they are ruled with a diamond by the aid of a dividing machine; and in late years, particularly in the hands of Rutherfurd and Rowland, an extraordinary degree of perfection has been attained. It was many years ago—nearly twenty-five, I am afraid—that I first began experiments upon the photographic reproduction of these divided gratings, each in itself the work of great time and trouble, and costing a good deal of money. At that time the only gratings available were made by Nobert, in Germany, of which I had two, each containing about a square inch of ruled surface, one of about 3000 lines to the inch, and the other of about 6000. It happened, accidentally, that the grating with 3000 lines was the better of the two, in that it was more accurately ruled, and gave much finer definition upon the solar spectrum; the 6000-line grating was brighter, but its definition was decidedly inferior; so that both had certain advantages, according to the particular object in view.

If it comes to the question of how to make a grating by photography, probably the first idea to occur to one would be that it might be a comparatively simple matter to make a grating upon a large scale, and then reduce it by photography; but if one goes into the figures, the project is not found so promising. Take, for instance, a grating with 10,000 lines to the inch; if you magnified that, say, 100 times, your lines would then be 100 to the inch; if you magnified it 1000 times, they would still be 10 to the inch, and that would be a convenient size, so far as interval between the lines was concerned; but think what would be the area required to hold a grating magnified to that extent. By the time you have magnified the inch by 100 or 1000, you would want a wall of a house or of a cathedral to hold the grating. If the problem were proposed of ruling a grating with 6000 lines to the inch, with a high degree of accuracy, it would be easier to do it on a microscopic scale than upon a large scale, leaving out of consideration the difficulty of reproducing it. And those difficulties would be insuperable, because, although with a good microscopic object-glass it would be easy to photograph lines which would be much closer together than 3000 or 6000 to the inch, yet that could only be achieved over a very small area of surface—nothing like a square inch; and if it were required to cover a square inch with lines 6000 to the inch, it would be beyond the power, not only, I believe, of any microscope, but of any lens that was ever made. So that that line of investigation does not fulfil the promise which at first it might appear to give; and, in fact, there is nothing simpler or better than to copy the original ruled by a dividing engine, by the simple process of contact printing.

For this purpose some precautions are required. You must use very flat glass, by preference it should be optically worked, although very good results may be obtained on selected pieces of ordinary plate. Of course, no one would think of making such a print by diffused daylight; but the sun itself, or a point of light from any suitable source, according to the nature of the photographic process which is adopted, permits quite well of the reproduction of any grating of a moderate degree of fineness. I have used almost all varieties of photographic processes in my time. In the days when I first worked, the various dry collodion processes were better understood than they are now; the old albumen process was extremely suitable for such work as this, on account of the almost complete absence of structure in the film, and the very convenient hardness of the surface, which made the finished result comparatively little liable to injury. I used with success the dry collodion processes, the tannin process among others, and also some of the direct printing methods, such as the collodio-chloride. The latter method, worked upon glass, gave excellent results, particularly if the finished print was treated with mercury in the way commonly used for intensification, except that, in the treatment of a grating with mercury, it is desirable to stop at the mercury, and not to go on to the blackening process used in the intensification of negatives. From the visual point of view, the grating, after intensification—if one may use the term—with mercury, looks much less intense than before, but, nevertheless, the spectra seen when a point or slit of light is looked at through the grating become very much more brilliant.

I used another process at that time, more than twenty years ago, which gave excellent results, but had not the degree of certainty that I aimed at, namely, a bichromated gelatine process, similar to carbon printing, except that no pigment was employed. A glass plate was simply coated with bichromated gelatine of a suitable thickness—and a good deal depended upon hitting that off correctly; if the coating was too thin the grating showed a deficiency of brightness, whereas, if it was too thick, there might be a difficulty in getting it sufficiently uniform and smooth on the surface. However, I obtained excellent gratings by that process, most of them capable of showing the nickel line between the two well-known sodium or D lines in the solar spectrum, when suitably examined. The collodio-chloride process was comparatively slow, and bichromated gelatine required two or three minutes' exposure to sunlight to produce a proper effect; but for the more sensitive developed negative processes a very much less powerful light or a reduced exposure was needed.

The performance of the copies was quite good, and, except where there was some obvious defect, I never could see that they were worse than the originals; in fact, in respect of brightness it not unfrequently happened that the copies were far superior to the originals, so that in many cases they would be more useful. I do not mean by that, however, that I would rather have a copy than an original if any one wanted to make me a present. There seems to be some falling off in copies; so that they cannot well be copied again, and if you want to work upon spectra of an extremely high order, dispersed to a great extent laterally from the direct line, a copy would not be satisfactory. The reproduction of gratings on bichromated gelatine is easily and quickly accomplished; there is only the coating of the glass over-night, rapid drying to avoid crystallisation in the film, exposure, washing, and drying. In order to get the best effect it is usually desirable to treat the bichromated copies with hot water. It is a little difficult to understand what precisely happens. All photographers know that the action of light upon bichromated gelatine is to produce a comparative insolubility of the gelatine. In the carbon process, and many others in which gelatine is used, the gelatine which remains soluble, not having been sufficiently exposed to light, is fairly washed away in the subsequent treatment with warm water; but for that effect it is generally necessary to get at the back of the gelatine film, because on its face there is usually a layer which is so insoluble as not to allow of the washing away of any of the gelatine to be found behind. But in the present case there is no question of transferring the film, which remains fixed to the glass, and therefore it is difficult to see how any gelatine could be dissolved out. However, under the action of water, the less exposed gelatine no doubt swells more than that which has received more exposure and has thus lost its affinity for water; and while the gelatine is wet it is reasonable that a rib-like structure should ensue, which is what would be required in order to make a grating, but when the gelatine dries, one would suppose that all would again become flat, and indeed that happens to a certain extent. The gratings lose a great deal of intensity in drying, but, if properly treated with warm water, the reduction does not go too far, and a considerable degree of intensity is left when the photograph is dry.

Although it belongs to another branch of the subject, a word may not be out of place as to the accuracy with which the gratings must be made. It seems a wonderful thing, at first sight, to rule 6000 lines to an inch at all, if you think of the smallest interval that you can readily see with the eye, perhaps one-hundredth of an inch, and remember that in these gratings there are sixty lines in a space of one-hundredth of an inch, and all disposed at rigorously equal intervals. Those familiar with optics will understand the importance of extreme accuracy if I give an illustration. Take the case of the two sodium lines in the spectrum, the D lines; they differ in wave-length by about a thousandth part; the dispersion—the extent to which the light is separated from the direct line—is in proportion to the wave-length of the light, and inversely as the interval between the consecutive lines on the grating; so that, if we had a grating

[1] An address delivered by Lord Rayleigh at the eighth annual conference of the Camera Club.

in which the first half was ruled at the rate of 1000 to the inch, and the second half at the rate of 1001 to the inch, the one half would evidently do the same thing for one soda line as the other half of the grating was doing for the other soda line, and the two lines would be mixed together and confused. In order, therefore, to do anything like good work, it is necessary, not only to have a very great number of lines, but to have them spaced with most extraordinary precision; and it is wonderful what success has been reached by the beautiful dividing machines of Rutherfurd and Rowland. I have seen Rowland's machine at Baltimore, and have heard him speak of the great precautions required to get good results. The whole operation of the machine is automatic; the ruling goes on continuously day and night, and it is necessary to pay the most careful regard to uniformity of temperature, for the slightest expansion or contraction due to change of temperature of the different parts of the machine would bring utter confusion into the grating and its resulting spectrum.

In printing, the contact has to be pretty close. and the finer the grating the closer must the contact be. I experimented upon that point by preparing a photographic film upon a slightly convex surface, and using that for the print; then, where the contact was closest, the original of course was very well impressed, and round that, one got different degrees of increasingly imperfect contact, and one could trace in the result what the effect of imperfect contact is. I found that, both with gratings of 3000 and 6000 lines to the inch, good enough contact was obtained with ordinary flat glass; but when you come to gratings of 17,000 or 20,000 lines to the inch the contact requires to be extremely close, and in order to get a good copy of a grating with 20,000 lines per inch it is necessary that there should nowhere be one ten-thousandth of an inch between the original and the printing surface—a degree of closeness not easily secured over the entire area. It is rather singular that though I published full accounts of this work a long time ago, and distributed a large number of copies, the process of reproducing gratings by photography did not become universally known, and was re-discovered in France, by Isarn, only two or three years since.

One reason why photographic reproduction is not practised to a very great extent is. that the modern gratings—such as Rowland's—are ruled almost universally upon speculum metal. A grating upon speculum metal is very excellent for use, but does not well lend itself to the process of photographic copying, although I have succeeded to a certain extent in copying a grating ruled upon speculum metal. For this purpose the light had to pass first through the photographic film, then be reflected from the speculum metal, and so pass back again through the film. Gratings such as could easily be made by copying from a glass original are not readily produced from one on speculum metal, and I think that is the reason why the process has not come into more regular use. Glass is much more trying than speculum metal to the diamond, and that accounts for the latter being generally preferred for gratings; indeed, the principal difficulty consists in getting a good diamond point, and maintaining it in a shape suitable for making the very fine cut which is required.

I may now allude to another method of photographic reproduction which I tried only last summer. It happened that I then went with Prof. Meldola over Waterlow's large photo-mechanical printing establishment, and I was very much interested, among many other very interesting things, in the use of the old bitumen process—the first photographic process known. It is used for the reproduction of cuts in black and white. A carefully cleansed zinc plate is coated with varnish of bitumen dissolved in benzole, and exposed to sunlight for about two hours under a negative, giving great contrast. Where the light penetrates the negative the bitumen becomes comparatively insoluble, and where it has been protected from the action of light it retains its original degree of solubility. When the exposed plate is treated with a solvent, turpentine or some solvent milder than benzole, the protected parts are dissolved away, leaving the bare metal; whereas the parts that have received the sunlight, being rendered insoluble, remain upon the metal and protect it in the subsequent etching process. I did not propose to etch metal, and, therefore, I simply used the bitumen varnish spread upon glass plates, and exposed the plates so prepared to sunshine for about two hours in contact with the grating. They are then developed, if one may use the phrase, with turpentine; and this is the part of the process which is the most difficult to manage. If you stop development early you get a grating which gives fair spectra, but it may be deficient in intensity and brightness; if you push development, the brightness increases up to a point at which the film disintegrates altogether. In this way one is tempted to pursue the process to the very last point, and, although one may succeed so far as to have a film which is quite intact so long as the turpentine is upon it, I have not succeeded in finding any method of getting rid of the turpentine without leading to the disintegration of the film. In the commercial application of the process the bitumen is treated somewhat brutally—the turpentine is rinsed off with a jet of water; I have tried that, and many of my results have been very good. I have also tried to sling off the turpentine by putting the plate into a kind of centrifugal machine; but by either plan the film in which the development has been too far pushed, is liable not to survive the treatment required for getting rid of the turpentine. If the solvent is allowed to remain we are in another difficulty, because then the developing action is continued and the result is lost. But if the process is properly managed, and development stopped at the right point, and if the film be of the right degree of thickness, you get an excellent copy. I have one here, 6000 lines to the inch, which I think is about the very best copy I have ever made. The method gives results somewhat superior to the best that can be got with gelatine; but I would not recommend it in preference to the latter, because it is very much more difficult to work unless some one can hit upon an improved manipulation.

I will not enlarge upon the importance of gratings; those acquainted with optics know how very important is the part played by diffraction gratings in optical research, and how the most delicate work upon spectra, requiring the highest degree of optical power, is made by means of gratings, ruled on speculum metal by Rowland. I suppose the reason why no professional photographer has taken up the production of photographic gratings, is the difficulty of getting the glass originals; they are very expensive, and I do not know where they are now to be obtained. It seems a pity that photographic copies should not be more generally available. I have given a great many away myself; but educational establishments are increasing all over the country, and for the purpose of instructing students it is desirable that reasonably good gratings should be placed in their hands, to make them familiar with the measurements by which the wave-length of light is determined.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. STANLEY DUNKERLEY has been appointed to the University Demonstratorship of Mechanism and Applied Mechanics at Cambridge, made vacant by the election of Mr. Dalby to the Professorship of Mechanical Engineering at Finsbury College.

AMONG the recipients of honorary degrees, conferred at the close of the summer session of the University of Edinburgh on Saturday, were Prof. Francis A. Walker. President of the Massachusetts Institute of Technology, and Sir Dietrich Brandis, K.C.I.E., F.R.S., late Inspector-General of Forests in India.

DR. J. D. PORTER, of Columbia College, New York, has been appointed to the newly-founded Macdonald chair of Mining and Metallurgy in the M'Gill University, Montreal. Mr. Herbert W. Umney, of Bath, has been appointed Assistant-Professor of Civil Engineering.

THE Council of the Hartley Institution, Southampton, have just made the following appointments:—Lecturer in Mathematics, Dr. Cuthbert E. Cullis, Assistant Lecturer to Prof. Karl Pearson, University College, London. Lecturer in Chemistry, Dr. D. R. Boyd, Demonstrator and Assistant Lecturer in Chemistry, Mason College, Birmingham. Lecturer in Biology and Geology, Mr. E. T. Mellor, Assistant Demonstrator in Biology, Owens College, Manchester.

HER MAJESTY'S Commissioners for the Exhibition of 1851 have made the following appointments to Science Research Scholarships, for the year 1896, on the recommendation of the authorities of the respective Universities and Colleges. The scholarships are of the value of £150 a year, and are ordinarily tenable for two years (subject to a satisfactory report at the end of the first year) in any University at home and abroad, or in some other institution approved of by the Commissioners. The

scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country. The nominating institutions and the scholars are as follows:—University of Glasgow, W. C. Henderson; University of Aberdeen, A. Ogg; Mason College, Birmingham, T. S. Price; University College, Bristol, E. C. Fortey; Yorkshire College, Leeds, H. M. Dawson; University College, Liverpool, H. E. Annett; University College, London, J. E. Petavel; Owens College, Manchester, J. L. Heinke; Durham College of Science, Newcastle-on-Tyne, J. A. Smythe; University College, Nottingham, G. B. Bryan; University College of Wales, Aberystwyth, S. W. Richardson; University College of North Wales, Bangor, D. Williams (conditional appointment); Queen's College, Galway, J. Henry; University of Toronto, A. M. Scott; Dalhousie University, Halifax, Nova Scotia, D. McIntosh; University of New Zealand, J. A. Erskine.

The following scholarships granted in 1895 have been continued for a second year on receipt of a satisfactory report of work done during the first year:—

Nominating institution.	Scholar.	Places of study.
University of Glasgow.	W. Stewart.	Universities of Glasgow and Berlin.
University of St. Andrews.	H. C. Williamson.	Marine Laboratories, Naples and Kiel.
University College, Dundee.	J. Henderson.	Polytechnicum, Munich.
University College, Liverpool.	J. T. Farmer.	MacDonald Engineering Laboratories, Montreal.
University College, London.	E. Aston.	University College, London, and University of Geneva.
Durham College of Science, Newcastle-upon-Tyne.	A. L. Mellanby.	MacDonald Engineering Laboratories, Montreal, and Durham College of Science.
University College, Nottingham.	M. E. Feilmann.	Polytechnicum, Zürich.
Queen's College, Belfast.	W. Hanna.	Laboratory of Royal College of Physicians and Surgeons, London, and Bacteriological Institute, Prague.
McGill University, Montreal.	R. O. King.	MacDonald Engineering Laboratories, Montreal. (To change for second year.)
Queen's University, Kingston, Canada.	T. L. Walker.	University of Leipzig.
University of Sydney.	J. A. Watt.	Royal College of Science, South Kensington.
University of New Zealand.	E. Rutherford.	Cavendish Laboratory, University of Cambridge.

A limited number of the scholarships are renewed for a third year when it appears that the renewal is likely to result directly in work of scientific importance. The following scholarships granted in 1894 have been renewed for a third year:—

Nomina g institution.	Scholar.	Places of study.
Universi of Edinburgh.	J. C. Beattie.	Universities of Vienna and Berlin.
University of Aberdeen.	W. B. Davidson	Universities of Würzburg and Leipzig.
University College, Liverpool.	Dr. A. J. Ewart	University of Leipzig and Botanical Institute, Java.
University of Toronto.	Dr. F. B. Kenrick.	University of Leipzig.

Generous gifts to educational institutions in America have often been noted in these columns. The New York *Critic* has collected some valuable information concerning the total amounts of such gifts and legacies received from various benefactors. Perhaps the following summary of these encouragements will create a spirit of emulation in the wealthy men of the British Isles before whom it may come. George Peabody, various, £1,035,000. Stephen Girard, Girard College, present value about £3,000,000. John D. Rockefeller, University of Chicago, £1,485,200; Vassar College, £20,000; Barnard College, £5000. Miss Helen Culver, University of Chicago, £205,000. Leland Stanford, Leland Stanford Junior University, from £3,000,000 to £4,000,000. Johns Hopkins, Johns Hopkins University, over £600,000. John C. Green, Princeton College and Lawrenceville School, £600,000. Anthony J. Drexel, Drexel Institute, £600,000. Asa Packer, Lehigh University, 115 acres of land and £500,000. Charles Pratt, Pratt Institute, £540,000; Charles M. Pratt, £8000. Leonard Case, Case School of Applied Science, £400,000. Henry W. Sage, Cornell University, £234,000. Cornelius Vanderbilt (deceased), Vanderbilt University, £200,000; William H. Vanderbilt, £92,000; Cornelius Vanderbilt, £8000. Peter Cooper and his family, Cooper Union, £330,189. Paul Tulane, Tulane University, £210,000. Seth Low, Columbia University, £200,000; Barnard College, £2000. Washington C. De Pauw, De Pauw University, £200,000. James Lick, University of California, £150,000. Isaac Rich, Boston University, £140,000. Ezra Cornell, Cornell University, £134,000. J. Pierpont Morgan, New York Trade School, £100,000. Colonel and Mrs. Richard T. Auchmuty, New York Trade School, £82,000. The total of this list, which is probably not complete, amounts to £15,080,389.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, July.—The "International Cloud Atlas." Mr. Symons takes the opportunity offered by the publication of this work (of which only a very few copies have yet been distributed) to make a brief reference to the principal works on clouds which have recently preceded the present one, including M. Weilbach's "Nordeuropas Skyformer" (Copenhagen, 1881), the "Wolken-Atlas" of MM. Hildebrandsson, Köppen, and Neumayer (Hamburg, 1890), M. Singer's "Wolkentafeln" (Munich, 1892), "Classificazione delle nubi" by the Specola Vaticana, containing some excellent reproductions of M. Mannucci's photographs (Rome, 1893), and the Rev. W. Clement Ley's "Cloudland" (London, 1894). The "International Cloud Atlas" (Paris, 1896) has been prepared under the superintendence of the International Meteorological Committee, and contains twenty-eight coloured reproductions of clouds. Although none of them is from an English photograph, Mr. Symons thinks our countrymen may be well content to see how largely the international system of 1896 is based upon the work of Luke Howard, and that the classification adopted is practically that of the joint work of Dr. Hildebrandsson and the Hon. Ralph Abercromby.—The spring drought of 1896. Mr. Symons selected twenty-eight stations distributed over the United Kingdom; these show that the rainfall for the first half of the year at eight out of sixteen English and Welsh stations, the total fell below two-thirds of the average, the lowest values being 48 per cent. at Haverfordwest; while for the Scotch and Irish stations the average was 83 per cent. and 80 per cent. respectively. The results for April and May show that at three stations the rainfall was less than 20 per cent. of the average, the total in London being 19 per cent. In 1893 the drought was more severe in parts of England and Wales, but the 1896 drought in the south of Ireland appears to be unprecedented; at Cork it lasted for sixty-four days.

The numbers of the *Bulletino della Società Botanica Italiana* for May–July contain, in addition to papers of more local interest, one by Prof. G. Arcangeli on the elongation of the organs of aquatic plants (chiefly *Nymphæaceæ*), in which he expresses the opinion that the stress due to the weight of the superposed liquid is the chief stimulus for their adaptation to the depth of the water in which they live. The same author has a note on the sleep of plants, and the benefits which they derive from the varying positions of the leaves by night and by day.

The contents of the *Nuovo Giornale Botanico Italiano* for July comprise four papers, of which the titles only can be given:—The conclusion of Sig. L. Nicotra's exhaustive essay on the statistics of the Flora of Sicily; Sig. A. Lentiechia on morphological variations in wild and cultivated plants; Sig. F. Tasci on the mycology of the Province of Sienna; Sig. U. Martelli on a new species of *Centaurea* (*C. ferulacea*).

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 18.—"The Determination of the Freezing-point of Mercurial Thermometers." By Dr. J. A. Harker.

The method adopted is to cool distilled water in a suitable vessel to a temperature below 0°, to insert the thermometer,

and then bring about the freezing of the water by dropping in a crystal of ice. The thermometer then rises, and finally attains a steady temperature, differing only very slightly from the true zero.

The apparatus employed consists of two portions, the thermostat and the cooler. The former is a copper vessel, filled with either refined petroleum or a strong solution of common salt. This vessel communicates with the cooler, through which the liquid can be pumped by a rotary stirrer; and by this means it can be cooled and maintained for some time at about −2°. The distilled water to be frozen is contained in a glass tube of about 300 c.c. capacity. This is first placed directly into the circulating liquid, and cooled quickly to −0·5° or −0·7°. It is then transferred to a cylinder lined with polished metal, placed in the centre of the thermostat. The thermometer whose zero is to be taken is then quickly fixed in position, the bulb and a considerable length of the stem above the zero being immersed in the water. A crystal of ice is dropped in, and the temperature quickly rises to the freezing point.

Experiments made with good mercurial thermometers showed that if ice be present in sufficient quantity, the final temperature attained by the mixture of ice and water is not influenced perceptibly by variation of the temperature of the circulating liquid within fairly wide limits. As, however, it seemed desirable to control this result by some other means, a platinum thermometer and bridge were designed, capable of indicating with certainty a change of 0·0001°, and a description of the whole arrangement employed to attain this degree of accuracy forms the second half of the paper. The resistances in the bridge were of manganin, and the thermometers were provided with the compensating leads, devised by Mr. Callendar. The maximum current which can be used in accurate measurements with these thermometers is about 0·02 ampere, and therefore the galvanometer employed required to be extremely sensitive. The instrument selected was a low resistance astatic one with vertical needle system, and gives at the greatest working sensibility one scale division for 1×10^{-10} ampere.

With this arrangement the influence of various conditions on the final temperature attained by the mixture of ice and water was studied. The results were found to be in close agreement with the theoretical deductions of Nernst, and it was quite easy to keep the temperature in the freezing vessel constant to within one or two ten-thousandths of a degree for an hour at a time.

The conclusion drawn from the previous experiments made with mercurial thermometers as to the small influence of changes in the external temperature, and in the temperature of the circulating liquid on that of the freezing vessel, was also confirmed, and it was found that a change of two or three degrees in the temperature of the circulating liquid only caused the temperature of the mixture in the tube to alter by three or four ten-thousandths.

EDINBURGH.

Royal Society, July 20.—The Hon. Lord M'Laren in the chair.—Prof. Tait gave a brief description of a paper by Lord Kelvin on the different configurations possible with the same law of force according to Boscovich. In previous papers the author had confined himself to a treatment of the nature of configuration. This paper was a daring application of principle towards a rational explanation of crystalline form, having regard to the mutual forces involved.—Prof. Ludwig Boltzmann's communication, read by Prof. Tait, on the importance of Clerk-Maxwell's contributions to the kinetic theory of gases, consisted of a few sentences setting forth the writer's high respect for Clerk-Maxwell, and defining his relations with M. Bertrand. The paper in full was promised later.—Dr. Halm read an abstract of his paper on theoretical researches on the daily change of the temperature of the air. The fundamental differential equations of the problem, so far as they concern the curve of temperature during night, were first propounded by A. Weilenmann, in his essay, "Ueber den taeglichen Gang der Temperatur zu Bern" (*Schweizerische Meteorol.*, Beobachtungen ix., 1872), which may be considered as the first successful attempt at investigating the question from a theoretical point of view. But the physical explanation of his mathematical terms being insufficient, the author undertakes to show that these equations are in perfect agreement with the fundamental laws of radiation and conduction of heat, as given by Fourier and many others. The general question, by what means does the lowest layer of the atmosphere, the temperature of which is recorded by our thermometric instruments, receive or lose heat, may be answered by this result. Every change of temperature is caused by continuous radiation between the soil and an unknown part of the atmosphere—for which, however, there can be substituted, under all circumstances, two masses of air with the same coefficient of radiation, one of these having the variable temperature of the observed lowest layer; the other, a constant temperature. The next part of the paper consisted in proving that Weilenmann's equations, by a proper application of the sun's radiating power at every moment during the day, can be used for deriving an integral which gives expression to the change of the temperature during the time from sunrise to sunset. This integral consists of two different parts, one of which contains two arbitrary constants, naturally involved by the process of integration; the others are functions of time introduced by the law of solar radiation on a horizontal surface. But it can easily be proved that both the arbitrary constants have to disappear in every case, so that the change of temperature appears to be regulated simply by functions directly depending on the radiating power of the sun. Considering the fact that the conditions of radiation must be importantly influenced by various systematical disturbances, such as convection currents, the continuous change of the quantity and quality of atmospheric moisture, the state of cloudiness and the physical conditions of the soil, great importance has to be laid on the question how these may be given expression to in the fundamental equations of the problem. As far as the convection currents are concerned, their influence is shown to be in perfect agreement with observations, the range of temperature being diminished, and the time of maximum being brought nearer to the culmination of the sun when the direction of the current is from a cold quarter; the opposite being the case when from a warm one. The effect of sea-breezes is an example of the former condition; that of currents flowing from a mountain to the valley during daytime, an example of the latter. The very considerable effect of the daily change in the amount of atmospheric moisture, which has been deduced from direct observation of clouds and the absolute humidity of the air, complicates the theoretical equation by adding a new term, the parameters of which can be shown to be in full agreement with these observations. The most important branch of the subject treated in the paper was the determination of the solar constant from the *daily* temperature observations, which, after the influence of the state of cloudiness and the change of the physical conditions of the soil therefrom resulting, have been investigated, show values sufficiently accurate to admit of examining the question of the periodicity of solar radiation by a method the advantages of which seem obvious compared with the commonly used method founded on study of mean *annual* temperatures. From a large number of stations in Austria and Hungary, whose observations, extending over the years 1876–93, have been used, the author shows a close correspondence between the inverted curve of sun-spots and that of solar radiation. A much fuller investigation, however, extending over a longer series of years, and embracing a greater extent of territory, is required to finally establish the results deduced.—Prof. J. M. Dixon, of St. Louis, described in an interesting and popular manner the tornado which recently visited that city, and of which he was an eye-witness. The report already given in NATURE (vol. liv. p. 104) he characterised as correct.—Mr. Robert Kidston read a paper describing some cones of *Sigillarii*, in which the structure of the sporangia was shown. The sporangia appeared to be immersed in the bracts in a somewhat similar manner to that which occurs in *Isoetes* showing that the affinities of *Sigillarii* are with *Isoetes*, as conjectured by Goldenberg. Two new species of Sigillarian cones (*Sigillariostrobus*) were described, and a new species of *Sigillaria*.—Prof. Charteris read a short paper on the physiological action of eucaine. He claimed for this new antiseptic, which he described merely as a compound synthetically prepared, that it was not so toxic as cocaine, while the anæsthesia it produced was as complete. It did not contract the pupil when applied to the eye, and a solution in water did not decompose.—The Chairman, in a few words, reviewed the work of the past session, and held out hopes of further prosperity and usefulness in the future.

PARIS

Academy of Sciences, July 27.—M. A. Cornu in the chair.—On the water-spout of July 26, at the Museum of Natural History, by M. Milne-Edwards. An account

of the disastrous effects upon the Museum produced by this water-spout.—On some new experiments relating to the preparation of the diamond, by M. H. Moissan.—Study of the black diamond, by the same. Black diamond, reduced to a very fine state of division, and heated in a stream of oxygen to a temperature about 200° C. below the temperature of combustion of the diamond, gives off a very small amount of carbon dioxide, and the diamond remaining is transparent.—A Spanish truffle and three new truffles from Marocco, by M. Ad. Chatin. The new specimens are described as *Terfezia Mellerionis*, of Laroche, *Terfezia Leonis* (var. *heterospora*), of Laroche, and *Terfezia Boudieri*, of Mazogan.—On the homogeneity of argon and helium, by Prof. W. Ramsay and J. Norman Collie. By fractional diffusion through porous tubes, argon yields two portions, of which the lighter has a density of 19·93, the heavier of 20·01. Similar experiments with helium gave densities of 1·874 and 2·133 for the two extreme portions, results which were confirmed by measurements of the refractive indices by Lord Rayleigh. Both specimens gave spectra which were absolutely identical, and hence the possibility is suggested of there being here a true separation of light molecules from heavy molecules of the same substance.—On the mononitrile of camphoric acid, its anhydride and anilide, by MM. A. Haller and Minguin.—On a method for giving the exact direction of a sound signal, by M. E. Hardy. Two methods are given for effecting this at sea.—Note accompanying two memoirs on thermochemistry, by M. Langlois.—On the error of refraction in geometric levelling, by M. Ch. Lallemand. It is shown that the effect of the refraction of the air, which can generally be neglected or eliminated in triangulation, becomes quite appreciable in levelling, and a formula is developed for introducing the necessary correction.—On the distribution of the displacements in metals subjected to stresses, by M. G. Charpy. The suggestion of M. Hartmann that metals, in spite of their known heterogeneous structure, behave as homogeneous bodies, has been submitted to further experiments, with the result that the displacements vary from point to point, and correspond in all respects with the structure shown micrographically.—On the density and mean specific heat between 0° and 100° of the alloys of iron and antimony, by M. J. Laborde. The numbers found for the specific heats are all greater than those calculated from the assumption of simple mixture.—On the determination of the ratio of the specific heats of gases, by MM. G. Maneuvrier and J. Fournier. The final results are: for air 1·392, for carbon dioxide 1·299, for hydrogen 1·384.—Researches on the relations existing between the radiation of a body and the nature of the surrounding medium, by M. Smoluchowski de Smolan. An experimental study of the formula of Clausius, according to which the emission should be proportional to the square of the refractive index of the medium. The general result is to confirm the law of Clausius.—Cranial endography by means of the Röntgen rays, by MM. Remy and Contremoulins.—Study of the nitrogren and argon of fire-damp, by M. Th. Schlœsing, jun. Specimens of fire-damp collected with suitable precautions from many sources all contained nitrogen, showing a notable amount of argon: the ratio of argon to nitrogen was, within the limits of experimental error, about the same as in air.—On the preparation of selenic acid, by M. R. Metzner. This acid is readily obtained by oxidising dilute solutions of selenious acid with free permanganic acid.—On a new cobaltite, by M. E. Dufau. By heating magnesia and cobalt sesquioxide in the electric furnace a crystallised magnesium cobaltite, $MgCoO_3$ is obtained.—On the solutions of trichloracetic acid, by M. Paul Rivals. A thermochemical study of the dissociation of trichloracetic acid in solution.—On vinyl-trimethylene and ethylidene-trimethylene, by M. G. Gustavson.—On the constitution of pinacoline, by M. Maurice Delacre.—Crystallographic properties of some alkyl-camphors of the aromatic series, by M. J. Minguin.—Formation and etherification of crotonylic alcohol, by M. E. Charon.—On the electrolysis of the fatty acids, by M. J. Hamonet.—On several modes of preparation of the blue nitrosodisulphonic acid and its salts, by M. Paul Sabatier.—New observations on *Clythra quadripunctata*, by M. A. Lécaillon.—Influence of the reaction of the medium upon the activity of the oxidising ferment of mushrooms, by M. E. Bourquelot.—On a cellulose filter, by M. Henri Pottevin. A description of a cellulose filter capable of taking the place of the biscuit porcelain filter. Owing to the cheapness of material, instead of the cleaning process necessary for porcelain, a new disc can be used.—The mechanism of the extension of the blastoderm, and its relation to the eye of the fish, by M. E. Bataillon.—On the presence in the superior laryngeal nerve of secretory and vasculomotor fibres for the mucous membrane of the larynx, by M. E. Hédon.—On the physiological significance of direct cellular division, by MM. E. G. Balbiani and F. Henneguy.—Study of the gizzard in some *Blattidæ* and *Gryllidæ*, by M. Bordas.—The constitution of the phosphates of lime from Tunis, by M. L. Cayeux.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Student's Handbook of British Mosses: H. N. Dixon and H. G. Jameson (Eastbourne, Sumfield).—The G. E. R. Co.'s Tourist Guide to the Continent (London).—A Text-Book of Physical Exercises: Dr A. H. Carter and S. Bott (Macmillan).—La Distillation des Bois: E. Barillot (Paris, Gauthier-Villars).—Monthly Current Charts of the Indian Ocean (London).—Catalogue of the Described Diptera from South Asia: F. van der Wulp (Nijhoff, Hague).

Pamphlets.—Peabody Institute 29th Annual Report (Baltimore). Symbolism in American Art: F. W. Putnam and C. C. Willoughby (Salem, U.S.A.).

Serials.—Astronomical Observations and Researches made at Dunsink, 7th Part (Dublin, Hodges).—Longman's Magazine, August (Longmans).—Chambers's Journal, August (Chambers).—Proceedings of the Aristotelian Society, Vol. 3, No. 2 (Williams).—Proceedings of the Edinburgh Mathematical Society, Vol. xiv. THURSDAY, AUGUST 13, 1896.

TABLES FOR NAVIGATORS.

Azimuth Tables for the Higher Declinations (limits of declination 24° to 30°, both inclusive) between the parallels of latitude 0° and 60°, with Examples in the use of the Tables in English and French. By H. B. Goodwin, Naval Instructor, Royal Navy. Pp. xii + 74. London: Longmans, Green, and Co., 1896.)

A LEADING feature of present-day methods of navigation is the use of tables. There is scarcely any method in use in navigation for which one, and probably many, tables, of more or less practical utility, are not provided; and it would almost appear in some cases as though new methods had been proposed because tables could be prepared to use in connection with them, rather than because they were of real practical use. Some tables, such as those for "reduction to the meridian," may almost be regarded as luxuries, as they really save but little time and labour; though, on account of the easy adaptation of the formulæ to different forms of tabular computation, the number of them is large. On the other hand, there are tables which are really indispensable.

Of this latter class azimuth tables are a prominent type.

The object of the first of these azimuth tables, by Burdwood, published about a quarter of a century ago, was, to judge from the preface, merely to facilitate the calculation of compass error. Its publication, however, and that of its extension by Davis, may be said to have effected a revolution in the art of navigation, as Sumner's method, now so extensively used, was thereby rendered practically useful.

This method, of which the principle had been before recognised, was proposed by Captain Thomas Sumner, of Boston, in the year 1837. It enabled the navigator to determine *both* his latitude and longitude at *any* time, instead of being restricted to observations of the heavenly bodies, when near the prime vertical, for longitude; and when on or near the meridian, for latitude; observations for determining the latitude, in other cases, depending on a long process known as the "double altitude."

The principle of this method, as to which Lord Kelvin has remarked that every other method of navigation might be abolished so long as it was retained, is, that when the altitude of a heavenly body is observed, the observer must be situated somewhere on that small circle on the earth's surface which has the heavenly body as its pole. Another observation of the same body, when its azimuth has sufficiently changed, or of another body, at the same time, with an azimuth differing considerably from that of the first, places the observer, similarly, on another small circle. His actual position must therefore be at one of the two points of intersection of these circles; and. as these points are usually a long distance apart, his position, known approximately, will decide the question.

These circles, when transferred to a Mercator's chart, form regular curves, and the chords joining any two points on these curves within a few miles of each other, or the tangents to the curves through any points on them, such chords or tangents practically coinciding with the arcs, are called "lines of position." The intersection of two such "lines of position" fixes the position of the ship on the chart.

For the chord method the calculation of four longitudes would be necessary, *i.e.* two longitudes obtained from each of the altitudes with two assumed latitudes in the neighbourhood of the latitude by account; or else two longitudes and two latitudes when the heavenly body was near the meridian at the second observation. For the tangent method would be required two longitudes, or a longitude and a latitude, and two azimuths, as from the conditions of the problem, the tangent "line of position" must be at right angles to the heavenly body's azimuth.

Thus Sumner's method, though useful, was long and tedious, Captain Sumner himself remarking that the calculations would be much shortened and simplified if some ready means could be found of obtaining the azimuth of the body observed. This ready means is provided by Burdwood and Davis' tables. The longitude is calculated with the latitude by account; the azimuth taken from the tables, and the "position line" drawn through the position obtained. A second line is similarly drawn, the latitude being calculated, by reduction to the meridian, with the longitude by account, when the body observed is near the meridian, and the intersection of these two lines fixes the position of the ship.

Thus the cumbrous chord method is done away with, the tangent method is shortened and simplified. "Summer," therefore, almost deserves the character given to it by Lord Kelvin, especially as it is very usefu in high latitudes, in the winter months, during which the sun, when it does appear, is never very near the prime vertical, and the longitude obtained from observation of it is not so trustworthy.

Burdwood and Davis' azimuth tables give the true bearing or azimuth of any heavenly body whose declination lies between 0° and 23° north or south, for limits of latitude 0° to 60° north or south, for every four minutes of apparent time (in the case of the sun) or of hour angle (in the case of any other body). They are, therefore, most useful for obtaining the azimuth of any such body for compass error or line of position.

But the great increase in the speed of modern steamships necessitates more frequent observations in order to obtain the position of the ship. The correct position at noon each day was almost all that was required in the days of sailing ships and ships of low steam power. But now that ships may run 200 miles between noon and sunset on a summer's day, and considerably more between sunset and sunrise on a winter's night, it is necessary to know the position as often as possible, and strict orders are issued to the officer of the watch in Atlantic liners to omit *no* observation by which the ship's position may be determined.

Hence observations of the moon, the planets, and the stars are becoming of more frequent occurrence. One great advantage of observations of the moon is that it is frequently to be seen after sunrise or before sunset, and the position can be, therefore, readily fixed by simultaneous observations of the sun and moon (Sumner). Observations of the planets and stars can be made with *very* great accuracy in the twilight, and afford most satis-

factory results. There is, however, in the minds of many mariners an ill-defined idea that any problem not depending on the sun is too difficult to be meddled with. But so great a practical authority as Captain Lecky, in "Wrinkles on Navigation," says:

"For four or five months of the year navigation in our own latitudes is a much less ticklish affair when the stars are brought into action. In most cases they can be selected on or nearly on the prime vertical during twilight, and will therefore give a very reliable longitude."

The object of the present tables is to render Sumner's method applicable to the moon and planets in *all* cases, and to such bright stars as lie up to 30° of declination. The stars tabulated on page vii. of the preface are practically all available for longitude, and nearly all for latitude also.

The moon for about two-thirds of each month lies within the limits of "Burdwood and Davis," but for the remaining third it lies outside; and, as an example of a planet, Mars in 1896 has a higher northern declination than 23° from October 3 onwards.

When it is considered that the simultaneous observation of the sun and moon, already referred to, is admitted to be of great practical use even by those who are sceptical as to the general utility of observations of the moon, tables which permit Sumner's method to be applied to the moon at *all* times, at once establish their practical utility; and further, referring to the above-quoted opinion of Captain Lecky, it is to be remarked—

"That it is the very stars between 23° and 30° of declination (same name as latitude) which are particularly suitable for observation on the prime vertical, for the reason that in our latitudes such bodies have at the time a convenient altitude, whereas those of lower declination are too near the horizon when they have a bearing due east or west."

In this case again the practical value of the tables is obvious.

A somewhat interesting illustration of the value of observations of the stars is given in an article in the *Nautical Magazine* (June 1896). The article treats of the cross-currents said to be experienced in the Red Sea. Their existence was inferred from the discrepancy often noticed in the position of a ship as obtained from a.m. or p.m. observations of the sun. Recently, however, it has been considered that the discrepancy arises from the abnormal refraction experienced in the Red Sea, by means of which the position of the horizon is altered sufficiently to account for large errors in longitude.

In order to endeavour to settle the question numerous observations have been made, and the results tabulated. In a report on the subject by the Hydrographer of the United States, giving a detailed account of what has been done, the following paragraph occurs.

"The good agreement obtained between the results of the observation of dawn and twilight stars shows that excessive refraction is less frequent at those hours than at other hours of the day."

Tables, therefore, which tend to promote and simplify observations of the stars, when a ship is traversing a sea so full of dangers to navigation as the Red Sea has shown itself to be, should prove to be a boon.

In "Burdwood and Davis" the arguments are latitude, declination, and time. In the present tables "altitude" takes the place of "time" in the principal table. Table B is of use in the case of observations made when the altitude is greater than 55°, or is within 2° of the meridian altitude, the change in altitude being then so slow in comparison with the change of azimuth that it can no longer be regarded as a suitable argument. Table B is also of use in Sumner's method when an observation is made near the meridian, and the latitude calculated with an assumed longitude.

The use of altitude as an argument gives somewhat less minute results than the four-minute intervals, but there are great compensating advantages. The hour angle of the sun (or ship apparent time) is very readily found; but to find the hour angle of the moon, a planet, or a star, is a much more complicated matter. It involves a knowledge of ship time, right ascension of the sun, and right ascension of the body, presenting in addition a somewhat puzzling variety of cases. But the altitude of a star, &c., can be *accurately* observed in a few moments in the twilight when latitude or longitude is required, and can be observed with quite *sufficient* accuracy at any time, when visible, for the purpose of obtaining the azimuth or true bearing.

And this leads on to the second reason for the publication of these tables.

The process of observing the compass bearing of a bright star has been of late years very much facilitated by the introduction of Lord Kelvin's compass, so that the mariner has now the means of obtaining the error of his compass and of checking his deviation table at any time of the day or night when any of the heavenly bodies are visible. Here again we may quote Captain Lecky, who says: "It is perfectly wonderful how few men avail themselves of the stars on a fine night to see how their compasses are behaving." These tables, with the simple argument of a fairly correct altitude in place of a complicated hour angle, should render the practice of star observations for compass error as frequent as they are simple.

Such observation would appear to be most useful to the navigating officer of a ship of high speed, who may find that the variation has altered several degrees between sunset and sunrise. For example, in a ship steaming in the direction of New York, from latitude 45° N., longitude 60° W., it would be found that the variation had altered about 8° in a run of 300 miles, a distance that might very easily be traversed between such times as the sun was available for observation. It must therefore be of great assistance to the navigator that he should have a certain means of checking his compass error, not by the sun only, but by any heavenly body, of suitable and easily ascertained altitude, that may be visible.

Example iii. shows very clearly the value of the process (Examples i. and ii. showing the use of the tables as an aid to Sumner's method in the case of the stars and moon).

The methods for determining compass error show continual development. Formerly it was found by amplitude only, *i.e.* by the azimuth of the sun when its centre is on the horizon.

But, on account of refraction, the sun's centre appears to be about a diameter above the horizon when it is

really on it, and the correct position has to be guessed at. This never could be very satisfactory, and, in high latitudes with sun's declination of the same name, it is absolutely useless, as, owing to the small angle made by the path of the rising or setting sun with the horizon ($\cos^{-1}\{\sin \text{latitude} \cdot \sec \text{declination}\}$), the sun's azimuth may change several degrees while the altitude changes half a degree, so that it is practically impossible to estimate with any approximation to accuracy the correct amplitude; and when the sun's declination is greater than the co-latitude, the sun does not set at all.

Amplitude tables appear in all collections; but they might very well be dispensed with now that the compass error can be obtained with accuracy at any time of the day and night with the aid of "Burdwood and Davis," and the present extension to higher declinations.

In conclusion, a word of praise may be given to Messrs. Longmans for the clear and distinct manner in which the tables are printed. F. C. Stebbing.

CAVERNS AND THEIR INHABITANTS.

Les Cavernes et leurs Habitants. Par Julien Fraipont. Fcap. 8vo, pp. viii + 334. (Paris: Baillière et Fils, 1896.)

THE exploration of caverns during the twenty years which have passed since the publication of "Cave Hunting," has been carried on with an ever-increasing interest in various parts of the world. In France M. Martel has proved, by his adventurous descents into the abysses of these great laboratories of nature, that there is a charm in exploring them, similar to that which attracts the traveller to the highest summits of the mountains. If any one doubts this, let him read "Les Abîmes," where he will find a tale of descents into the principal European caverns that will remind him of the *Alpine Journal* turned upside down. In Central America the "Hill Caves of Yucatan" have allured Mr. Mercer to an expedition, the results of which have been recently published with admirable photographs. Here, as generally if not universally in the American caves, we look in vain for any traces of man older than the ancestors of the Indian tribes. In the book before us Prof. Fraipont, who had already made his mark as one of the discoverers of the human remains in the cave of Spy, deals with the general questions shortly and popularly, and with ample illustrations.

Our author treats, in the first place, the physical history of caverns, and divides them into those that have been formed by water and those which are of volcanic eruptive origin. In the first of these groups the caverns formed by the mechanical action of subterranean waters, combined with the chemical action of the carbonic acid in the water itself, are rightly separated from those formed by the erosive attack of the sea. The second group consists of those formed by the flow of liquid lava from a lava stream, after the upper parts and sides have cooled into the solid rocky condition. Caves of this sort are found in most volcanic areas, and notably in the island of Réunion and in Southern Italy. Prof. Fraipont classes with these the basaltic cave of Staffa, obviously the result of the attack of the waves on a line of weakness in the prismatic basalt. It is a sea cave pure and simple, and has no place in this group.

Prof. Fraipont, as might naturally be expected, passes by the present fauna of the caverns with a brief notice: the blind insects, the blind fish (*Amblyopsis*) of Kentucky and (*Lucifuga*) of Cuba, the blind *Proteus* of Carniola, and the large-eyed rat (*Neotoma*) of Kentucky that sees indistinctly. All these, so important from the light which they throw on the effect of the environment on their organisation, have no special interest in a work mainly given to the story of man in the Pleistocene caverns. To this we shall devote the rest of this review.

The Pleistocene caverns are treated from the usual standpoint of the French archæologist, and are divided into three groups, according to the alleged differences in the fauna and the occurrence of certain types of implements. (1) Those of the period of *Elephas antiquus* and *Rhinoceros merckii*, or the Chelles period; (2) those of the period of the mammoth and *Rhinoceros tichorrhinus*, or that of Moustier; and (3) those of the reindeer period. This classification is founded on the assumption that these mammalia and implements are characteristic of each division. Some animals preponderate in some caverns, and others in others, according to their habitat, and also according to the selection made by the hunters, who could kill, say, the reindeer more easily than the mammoth. As a matter of fact the study of the Pleistocene strata in France, as well as in Germany, Belgium and Britain, proves that all the above animals belong to one fauna in Pleistocene Europe. All have been found side by side in the gravel beds, for instance, on the banks of the Ouse at Bedford. The fact that the reindeer folk hunted the mammoth, as well as the rhinoceros, in France, is proved by the incised figures left behind as memorials of the chase. The differences in the implements, with the exception of the first, are probably local and due to tribal isolation, or to the scarcity or abundance of the materials for implement-making. The only two clearly-marked divisions, applicable to the whole of Europe, are (1) the Chelles period or that of the river-drift, and (2) that of the two latter of Mortillet (if Solutré be included, three) or that known to English archæology as that of the cave-men.

Human implements have been repeatedly met with in various caverns in France and Britain, and in the lower strata of Spy, in Belgium, which belong to the River-drift time; but with the exception of a solitary molar, found in one of the caves in the valley of the Elwy, no human remains have been discovered. It has been the good fortune of Profs. Fraipont and Lohest to find, in the cave of Spy, the first human skeletons, which belong beyond doubt to the cave-men, and are sufficiently perfect to allow of our arriving at a conclusion as to their physique. They are small with short arms and legs, and with a prognathous skull with low forehead, and enormous orbits overhung by strong superciliary ridges, with broad, strong cheek-bones, and with a long vault, similar to that of the skull of Neanderthal. They had small canines, and thigh-bones round in section, and without trace of platycnemism. Without accepting our author's view that they represent a "race humaine à caractères ethniques le plus inférieures que nous connaissons," we may conclude that they represent a family group of a

low type, which may be proved by future discovery to be a well-defined race, spread widely on the continent. We agree with him that the cave-men used fire-sticks, but we wait for further evidence before we can accept the conclusion that they were acquainted with the art of pottery-making. The cups, with round bottoms, found in the caves of Engis and Modave, are of the types met with in the lake-dwellings of Switzerland, such as Moringen and Concise, and are probably of Prehistoric and not of Pleistocene age. Nor can we accept his identification of the *Felis spelæa* with the tiger. It has been clearly shown in the Palæontographical Society's Memoirs, some twenty years ago, that it is a lion, differing from the tiger both in the shape of its skull and of its lower jaw. In treating of the range of this animal, our author has been unfortunate. In page 123 he tells us that "the great tiger of the caverns had disappeared in the Reindeer age," and, four pages later, that it was then alive. He speaks of it in one place as a tiger, in another as intermediate between a lion and a tiger, and in a third as an "extinct" type. His inclusion of the *Bos longifrons*, the goat, and the rabbit among the Pleistocene mammalia of France and Germany, is also open to doubt, the two first being probably introduced in the Neolithic age as domesticated animals, and the last having found its way northwards from Spain at a later time.

Although the Mammalia and, it may be added, the spelling of the names of places, people, and animals, are weak spots, the book may be summed up as an interesting addition to the literature of a complex and difficult subject, to which it forms a hand-book with valuable references. W. Boyd Dawkins.

THE PHOTOGRAPHY OF HISTOLOGICAL EVIDENCE.

Atlas of Nerve-cells. By M. Allen Starr, with the cooperation of Oliver S. Strong and Edward Leaming. Pp. x + 78. 53 plates. (Published for the Columbia University Press by Macmillan and Co., New York and London, 1896.)

"A CAREFUL drawing by a trained observer gives a better idea of appearances seen under the microscope than the best reproduction by photography can at present achieve." This statement was called forth by the consideration of a book similar in idea to the present, and apparently one of the same series, the "Atlas of Fertilisation and Karyokinesis of the Ovum," and was made a short time ago by Prof. Weldon in a notice of that book in Nature. It is forcibly recalled by the present book, the authors of which have been at the pains to present photographic representations of preparations showing nerve-cells, mostly prepared by the method of Golgi, any and all of which representations might with the greatest advantage, so far as clearness and facility of comprehension is concerned, have been replaced by a careful drawing of the cells which it was designed to illustrate.

The first idea that is evoked on looking at such plates as are here given, is that they are beautiful photographs of equally beautiful preparations. But the question *cui bono?* immediately forces itself upon one's mind. Are they intended to exhibit to other investigators the results of the author's investigations? This can hardly be the case, for it is not claimed that they show anything new, and every investigator can more or less readily make such preparations for himself. Are they intended for the student? This equally cannot be, since they are given in an expensive form, and are for the most part lacking in clearness; not from any fault in the preparations, but because the camera cannot be got to see more than one plane at a time. It is the hand which is constantly on the fine adjustment of the microscope that enables the shape of the body of a nerve-cell and the course of all its branches to be followed accurately, and it is only accidentally and imperfectly that these can be shown in a photograph.

The authors have themselves furnished the best possible illustration of the comparative value for teaching purposes of accurate drawings from good preparations, and of the best possible photographs from the same preparations, in giving (on p. 72, Fig. 10) a diagram of the cells of the cerebral cortex, "the cells being reproduced from the plates" (it would probably be more correct to say from the preparations). This diagram shows the cells with all their processes in relation to one another in the clear manner which we are accustomed to associate with representations of Golgi-preparations, and presents a marked contrast to the difficulty with which we make out some of the points which are stated to be shown in many of the photographs.

Moreover, as an account of the structure of the nervous system, which appears in some measure to be aimed at in this book, although not indicated in the title, the text which accompanies the plates is of no great value, since more complete and accurate accounts are within the reach of every student. It is indeed remarkable, considering that Dr. Allen Starr is the principal author, that quite serious errors, both of omission and of commission, should have found their way into the text. Thus, to take a single part of the nervous system, in a special enumeration of the connections of the cerebellum, the passage of the tract of Gowers into it by way of the superior peduncle—a fact indicated by Löwenthal and conclusively demonstrated by Mott—is ignored. On the other hand, the extensive descending degenerations described by Marchi, which have since been shown to have been produced in all probability by injuries to the bulb, accidentally made on removing the cerebellum, are still put forward as indicating an important centrifugal connection of the cerebellum with the spinal cord.

It may, further, be remarked that the present authors, like many others who have lately treated of the structure of the nervous system, have altogether failed to appreciate the importance of adopting for the nerve-cell a terminology which shall bring it into a line with all other cells in the body. Instead of speaking of the *body of the cell together with all its processes* as a "cell," they restrict the term cell to the body or nucleated part alone, and adopt the misleading term "neuron" to designate what is in fact the whole nerve-cell, ignoring the fact that νευρον literally means a sinew or fibre, and if applied

at all in this connection, should be restricted to the nerve-fibre process of the cell, for which they prefer the longer term *neuraxon!* Of course, as every one knows, our authors, in taking this course, are merely following the lead of a certain eminent German anatomist, it being a fashion with American scientific writers (except a few who prefer a sort of scientific Volapük) to follow pretty blindly all German scientific leads in the matter of nomenclature, and this even to the extent of bodily adopting actual German words into a language which can already find two or three synonyms for almost any word it may be desired to translate. No doubt many English authors are also to blame in this respect, but the fact is none the less to be deplored. And how can the average student be expected to understand the homologies of the nerve-cell if he is taught that he is not to call this particular unit a cell, like all the other units in the body, but is to restrict the term to a part of it only, for no other reason than the fact that when we were more steeped in ignorance of the structure of the nervous system than we are at present, that particular part of the nerve-cell was supposed to represent the whole!

Nevertheless, it may be freely admitted, in spite of the above criticisms, that many of the reproductions are extremely well done, and may with advantage be carefully studied by those who have not the opportunity of preparing for themselves specimens of like nature to those depicted. E. A. Schäfer.

OUR BOOK SHELF.

Flora der Ostfriesischen Inseln (einschliesslich der Insel Wangeroog). Von Prof. Dr. F. Buchenau. Dritte umgearbeitete Auflage. Small 8vo, pp. 205. (Leipzig: Wilhelm Engelmann, 1896.)

Dr. Buchenau is well-known as a botanical author for the simplicity and lucidity of his style, and the thoroughness with which he treats his subjects; and this little book is no exception to his usual work. Indeed, it is a model of what a local *Flora* should be, in striking contrast to the bulky barrenness of some of our English county *Floras*. It will easily go into the breast-pocket of a coat, and, as it contains descriptions and other information, it may be used, and be useful, in the field. The flora of the Frisian Islands is, on account of their situation, of great interest; and Dr. Buchenau has worked out its features, composition and peculiarities, with a full appreciation of its interest. An introductory chapter of some twenty-eight pages is a summary of the author's observations on various points; observations which have been published in full elsewhere, to which references are given. The paragraph on sand-binding plants is valuable. With regard to the flora as a whole, two principal points come under consideration, namely, its composition and origin. Taking into account the area, but more especially the slight elevation, the absence of trees, and almost so of shrubs, the flora is a comparatively rich one, and includes a number of species we should hardly expect to find. Dr. Buchenau says that the commonly accepted idea that the most interesting plants of the islands are relatively recent immigrants from the mainland of North-west Germany, will not bear investigation. "The most striking plants of the islands—*Liparis Lœselii*, *Gymnadenia conopsea*, *Epipactis latifolia*, *Parnassia palustris*, &c, are either wanting or exceedingly rare in East Friesland. They are only met with, by degrees, much further south. It is, therefore, inconceivable that they have migrated from the mainland in recent times, and assembled in these islands. The more probable explanation is that these plants are the remains of the old diluvial flora which from various causes have survived in the islands, though they have disappeared from the nearest mainland." I may add that Dr. Buchenau has made a special point of drawing up his descriptions, which are short and clear, from local forms. W. Botting Hemsley.

A Text-book of Physical Exercises adapted for the Use of Elementary Schools. By Dr. A. H. Carter and Samuel Bott. Pp. x + 168. (Macmillan and Co., Ltd., 1896.)

This book calls for notice in Nature because the exercises in it are founded upon a physiological basis. In a lucid introduction, Dr. Carter deals with "The Physiology of Exercise," and what he says should be read and digested by every teacher who has to do with the physical training of children. A knowledge of the structure and functions of muscular tissue is essential in order to fully appreciate the value of different exercises. For to know the physiological effects of exercise, the cause of fatigue, breathlessness, the nature of muscular stiffness, the reason why rest is necessary for the renewal of reserve force and the relief of muscular pains, is to possess the ability to judge the suitability of this or that exercise for the purpose of physical development.

Physical exercises have been carried out in the schools of the Birmingham School Board for the last ten years, and Mr. Bott, who organised and directs them, has, therefore, had ample opportunity of knowing the practical conditions of the exercises he describes. It is difficult to give clear and practicable instructions for the successful performance of such exercises as those with which the book deals, but, by means of concise text and numerous illustrations, this has been satisfactorily done. These instructions, and Dr. Carter's admirable lesson in physiology, will equip teachers with all they need know in order to carry out a sensible and systematic course of physical training for children.

Der Lichtsinn augenloser Tiere. By Dr. Wilibald A. Nagel. Pp. 120. (Jena: G. Fischer, 1896.)

Half of this interesting study is taken up by a paper on "Seeing without Eyes," in which the author considers the general question of sensitiveness to light, with illustrations from his own researches. In the second half these researches are described, and some special questions more fully discussed. The author's own observations were made chiefly on lamellibranchs and gasteropods, and showed a high degree of sensitiveness to light in the absence of anything like a visual organ. He found that some molluscs reacted especially to diminution, others to increase of light, and that this difference was correlated with other characters; those molluscs with soft shells, which bury themselves in the sand, reacted strongly to light, while those with hard shells responded more to shade. He found the highest degree of sensitiveness to light in Psammodia; and it is interesting to note, in relation to the common view as to the connection between sensitiveness to light and pigment, that the impregnated siphons of this mollusc were highly sensitive. Another interesting point investigated was the influence of repetition of a light stimulus. An oyster or mussel which has reacted to a shadow will react much less strongly, or not at all, to a second stimulus, even if much more intense, and does not recover its previous degree of excitability till more than an hour has elapsed. The book concludes with a full bibliography.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

PROF. LANKESTER (p. 245) has alluded to the dark pigment in the skin of tropical man as "conceivably . . . not in itself a useful, that is, a life-preserving or progeny-ensuring character, but merely the *accompaniment* of a power of resisting malarial germs . . ." residing in the leucocytes. This hypothetical case, used by Prof. Lankester for illustrating his argument, has been seriously entered upon by Mr. Thiselton-Dyer (p. 293), with the conclusion that "it does not follow that epidermal pigment is useless because one explanation of it seems to fail."

I beg permission to call attention to a paper in NATURE, vol. xxx. p. 401, by Surgeon-Major N. Alcock, "Why tropical man is black," which paper has seemed to me of great importance from the time I read it. Ingenuous considerations, together with quotations from various authorities, led Mr. Alcock to the opinion, that the dark pigment of tropical man's skin does serve as a protection against the rays of *light*. Whereas ". . . pigment placed behind a transparent nerve will exalt its vibrations to the highest pitch"—viz. in the eye—". . . the pigment in front of the endangered nerve reduces its vibrations by so much as the interrupted light would have excited, a quantity which . . . would, when multiplied by the whole area of body-surface, represent a total of nervous action that if continued would soon exhaust the individual and degrade the species."

In this way, the blackness of the negro which, as regards *heat* alone, must appear far from protective, will act as a screen against "the twin stimulant of life," light. "May it not, therefore, be claimed that there is much foundation for the suggestion that the black skin of the negro is but the smoked glass through which alone his wide-spread sentient nerve-endings could be enabled to regard the sun?"

There is no lack of evidence in support of this view. I will confine myself to mentioning a letter by Mr. Flinders Petrie (NATURE, vol. xxxiv. p. 76).

Perhaps I may remind the leaders in the old strife about the utility of specific characters, of the remarkable statements in "Descent of Man" (second edition, p. 61), commenting on the important concessions which, in the fifth edition of the "Origin of Species," Darwin has made to the views of Nägeli and others, concerning ". . . the existence of structures, which, as far as we can at present judge, are neither beneficial nor injurious . . ." DAVID WETTERHAN.

Freiburg, Badenia, August 1.

The Position of Science at Oxford.

IN the correspondence which your recent interesting article on this subject has evoked, the writers have mainly applied their criticism to particular aspects of the general argument raised. This is natural, for they have, scarcely without exception, been professionally interested in the teaching and progress of science, and their letters seem to show that an impression exists that there is a cause for blame in the matter, but that there is an uncertainty at whose door this blame should be laid. May I briefly examine the complaints which your original anonymous correspondent brought against the University authorities, and the present system in vogue at Oxford.

The first complaint has reference to the allotment of college scholarships to science. The argument may be admitted that strict justice demands that fifty-five scientific scholarships should be given; that only forty-four science scholars were last year in residence is incorrect. There were at least half-a-dozen men, receiving the emoluments of a nominally mathematical scholarship, who were preparing to take physics as a second school. Then, again, Christ Church annually gives an exhibition of the value of £85. If this be reckoned as equivalent to a scholarship, as in common fairness it should be reckoned, it is perfectly evident that it is not desirable to offer more scholarships in natural science until the school becomes larger, or the competition more severe than is at present the case. It is not unimportant to point out that an examination of the Natural Science Class Lists would show that some of the holders of these emoluments have not justified their selection.

The second part of the indictment against the college authorities is concerned with the appointment (or non-appointment) of science tutors. And in this matter your article is calculated to give a wrong impression, for it should be clearly understood that the college can exercise no compulsory power in choosing a course of study for any commoner. That commoner only can be influenced in this way, who starts his university career with no preference for a particular school, and it is inconceivable that such an one can ever really adorn any branch of study. But the man who knows what he wants to do, will find that he can get all the assistance he requires from his college lecturer, and that he is in no way worse off because the latter is not on the tutorial staff.

Your article contains a comparison between the conditions which obtain at Oxford and Cambridge respectively, much to the disadvantage of the former, and three reasons are given for the fact. First, at Cambridge scholarships are given to men of one year's standing; but if a man has failed to win a scholarship before his second term, it is not easy to see how he will qualify for one after a year's work. The fact that there is no lack of candidates of sufficient merit at Cambridge, is beyond a doubt largely accounted for by the fact that the scholarships are in many cases of smaller monetary value, and a lower standard is consequently expected. Secondly, a greater prestige attaches to the science school at Cambridge; and this is probably the greatest hindrance to an increase in the science school at Oxford. Time alone, by removing this ignorance and prejudice, can overcome the popular idea that science teaching is better, and, it might be added, cheaper in one university than in the other. At any rate, it cannot be said that Oxford collectively has not done her best to remove any inferiority she may have had in the past. The third argument is that the ranks of Oxford undergraduates are mainly recruited from the public schools, that science teaching in public schools is bad, and that the university is responsible. In fact, the essential argument of the article, and the only one that can possibly stand the test of criticism, is that the examination known as "responsions" urgently needs alteration, both in the direction of excluding the compulsory Greek test, and including an examination in the elements of natural science. Such an alteration, it is contended, would improve the science teaching, and it is the duty of the university to effect this reform.

The question of the Greek test is not new, and it cannot be denied that it has been considered and discussed with the utmost deliberation by those who have decided in favour of its retention. It is idle, in the face of facts, to throw a doubt on the sincerity of the University's good will towards science: it is equally impossible to deny, and it is admitted in your article, that the university is perfectly right to demand of its alumni a preliminary "fair general education"; at the same time, it would be difficult to name a body better qualified to decide what is a good general education than Convocation itself. The writer of your article appears to think that the dons—especially the younger dons—are foolish, childish, narrow-minded persons, absolutely ignorant of science and modern languages. This is, fortunately, far from true, and their deliberately expressed opinion, on a point of the greatest importance in public education, is assuredly entitled to some respect. Your correspondent complains that the knowledge of Greek demanded is too small to serve any useful purpose, and some of us may wish that the standard should be raised; but this complaint applies far more aptly to Cambridge than to Oxford. After all, a knowledge of Greek is insisted on because it is the most beautiful, the most expressive language ever written, and it contains the finest literature. A boy may forget how to conjugate a Greek verb (the sneer is rather hackneyed), but the reading of a Greek play, perhaps the most perfect form of literature the artist could use, will still have left a permanent effect on the mind of any one who is capable of culture. Besides, since a proper equivalent for Greek, even if a substitute be possible, will require as much time and as much application in its preparation, it is difficult to see in what way this alternative subject—be it German or any other—will prove more suitable, more convenient, or more congenial.

The question remains of making a knowledge of the elements of natural science compulsory in responsions, for compulsory it must be, if it is to change the existing state of things. The occasion for making this proposal is certainly unfortunate, for it evidently appears to be made not so much as an abstract suggestion for the improvement of education in general, as a scheme for the express purpose of improving the scientific teaching in schools. That it would have even this latter effect is open to

doubt, for mathematical teaching is almost as bad as scientific, although mathematics is compulsory in responsions. But it is clear enough that the proposal can only be defended on the former ground, for it would be preposterous to impose a useless burden on ninety-five per cent. of undergraduates, in order to raise the standard of a particular five per cent. Now, independently of the fact that the "elements of natural science" is a phrase very vague and difficult to define, it may be fairly urged that these "elements" consist of a series of interesting and important facts, of which, however, the connection and interaction is by no means apparent without a fairly comprehensive knowledge. It would be perfectly useless to have a knowledge of natural laws, when the idea of "law" is, in itself, entirely imperfect, as Helmholtz has held it to be in the unmathematical mind. A knowledge of science may be desirable, but equally so is a knowledge of history, or of English law. But if it be expedient to enlarge the scope of responsions in any way, it is abundantly clear that deeper, instead of wider, knowledge should be required: for example, the standard of mathematics might with good reason, perhaps, be raised.

One more remark seems needed in reply to your article. In attributing to the Greeks a true scientific spirit, your correspondent shows a strange and radical misconception of the tendency of Greek philosophic thought. The Hellenic spirit always inclined to speculative and metaphysical, as opposed to experimental philosophy, and Aristotle probably did more to retard our knowledge of natural science than any ten men have ever done to advance it.

The science school at Oxford may, and it is to be hoped will gradually improve, both in size and in quality; especially is there room for hope in the case of the medical school, though it is sadly handicapped by the absence of those opportunities for practical teaching which only a great hospital, situated in a crowded city, can afford. But it is useless to hope that the whole natural science school will ever become very large, so long as the tendency towards devolution and decentralisation in university (which ought to mean the highest) education continues. The principle of centralisation of educational forces, the enormous importance of which seems nowadays to be so lamentably lost sight of, possesses an especial validity in the case of scientific education. If this principle be neglected, it is our own fault if we find, on the one hand, a teaching staff of the highest order without pupils to instruct, and admirably equipped museums and laboratories standing practically idle and in abeyance; and, on the other hand, the best teachers so scattered up and down the country as to hinder the receptive student from gaining the advantages he would otherwise reap from their combined and systematised tuition. W. E. P.

Liverpool, August 3.

The Mandrake.

IN an anonymous work in Chinese, "Tiau-sieh-lui-pien" (1), nine plants are named as frequently to assume the human or animal figures, viz. cypress, Nan-tree,[1] turnip, mustard, citron, *Pachyma cocos*, *Lycium chinense*, *Phytolacca acinosa*, and *Panax Ginseng*.[2]

Of these nine, doubtless the Ginseng is the plant most celebrated for its medicinal virtues imaginarily connected with its anthropomorphous root (2); but as far as the multiplicity is in question of the legends talked of analogous to the mandrake-stories, certainly the Shang-luh (*Phytolacca acinosa*) is the most notorious one.

Under the heading at the beginning of this letter, I wrote to NATURE (vol. li. p. 608, April 25, 1895) a note on the analogies between the mandrake- and the Shang-luh-lores, pointing out the two instances, viz.:

(1) The roots of the two plants are said to have human shape.

(2) Both plants are said to have the power of shrieking.

Continuing in the research from that point, I have found further the additional points of analogy, that are as follows:—

[1] Some Japanese botanists (*e.g.* Matsumura, "Nippon Shokubutsu Meii," Tôkyô, 1884. p. 64) identify the Chinese "Nan" with the Euphorbiaceous plant, *Daphniphyllum macropodinum*; whether the identity is a sound one, I do not know.

[2] Most plants here enlisted, seem to have the alleged figures in their subterraneous members; only the citron might produce the fruits of such a configuration. As to the named trees, the cypress of Kien-ling was anciently valued for its wood, the veins of which represented naturally angels, clouds, men and animals ("Yuen-kien-lui-han," *op. cit.*, tom. ccccxiii. art. "Peh," 1); whereas the alleged human figure of the "Nan" was apparently formed by its stem and branches (*cf.* H. Ransdell, "Through Siberia," 1882, vol. i. p. 158).

(3) The Shang-luh is said to grow upon the ground beneath which dead man lies; and the mandrake is recorded to thrive under the gallows (3).

(4) When the Shang-luh is about to acquire the power of speech, *ignes fatui*, it is said, crowd about it (4). About the mandrake Richard Folkard remarks: "In an Anglo-Saxon manuscript of the tenth or eleventh century the mandrake is said to shine in the night like a candle. The Arabs call it the Devil's Candle because of this nocturnal shining appearance. . . ." (5)

(5) Chang Urh-Ki, a Chinese literatus of the seventeenth century, writes: "A sorcerer carves the root of Shang-luh into a human effigy, which he makes through his spells capable of telling the fortunes" (6). This forcibly brings to mind the old European belief in the diminutive prophetic images made out of mandrake-root[1] (7).

(6) The mandrake had a reputation that it makes men insane and the reason prisoner (8); correspondingly the red variety of Shang-luh[2] is described by Su Kung (*c.* 656) to be so poisonous as to cause men to see the demons (*i.e.* to make men delirious) (9).

(7) In "Pan-tsau-king," the oldest Chinese authority on materia medica, attributed to the mythical emperor, Shin-Nung, the Shang-luh is mentioned to kill the demoniacal beings; and, later, Teau Hung-King (452–536) speaks of its influence on the "Malignant Worms," which it drives out of the possessed (10), this efficiency being no doubt the principal reason for the Tauist usage of the white Phytolacca under the pseudonym of "Luh-fu" (or "Dried Venison") (11). Still later it is reputed by Ta-Ming (*c.* 968) to purge the "Poison of the *Ku*"[3] (12). Quite conformable to these is the ancient Jewish belief in the exorcising power the herb Baaras (or the mandrake) was renowned to possess (13).

(8) A recipe quoted by Chang Urh-ki from a "Book of Divine Physic" (14) seems to imply the old Chinese usage of the Shang-luh as philtre as much as the mandrake was highly esteemed therefor (15).

(9) "From the remotest antiquity the mandrake was reputed in the East to possess the property of removing sterility; hence Rachel's desire to obtain the plant that Reuben had found. . . ." (16). Now we read in a Chinese herbal that the black, ripe fruit of the Shang-luh is highly valued by rustic women, for it favours their fertility (17).

(10) Of the medicinal properties these plants are known to possess, some are common to both. Matthioli, referring to Galen, speaks as a cooling stuff of the mandrake (18), Li Shi-Chin assigning the same character to the Shang-luh (19). Both herbs were famed for their purgative functions, and both were applied to indolent and scrofulous tumours, and to swellings of the glands (20).

[1] From their traditions, the Chinese appear to have had about the Fung (*Liquidamber Maximowiczii*) two points of analogy to the mandrake-lore. First, Jin Fang's "Shuh-i-ki" (written sixth century, A.D., ed. Wang, tom. ii. fol. 10, *b*) contains the following passage: "In Nan-Chung there is the 'Liquidamber-Elf' (Fung-sze-kwei), which is the old tree of the named species transformed to man in its shape. Second, other authorities say a tumour develops upon the old Liquidamber; after a thunderstorm it elongates to three or five feet in length. Now the sorcerer carves this tumour to a human effigy to play black art thereby in a similar manner to the practice with the Shang-luh. However, in case a proper formula is not observed while gathering it, the tumour flies away and never serves the purpose (*cf.* Ki Ngan, "Nan-fang-tsau-muh-chwang," fourth century, A.D., Brit. Mus. copy, 15255, *a.* 5, tom. ii. fol. 1, *a*; Wu Ki-Siun, *op. cit.*, tom. xxxv. fol. 2 *a*; Sie Tsai-Kang, *op. cit.*, tom. x. fol. 4). Whether related to the latter belief or not, I remember some old men in Japan ever extolling the merits of images of Daikoku, the god of riches, artificially formed out of tumours on *Gingko biloba*.

[2] That is, the variety with its calyx coloured pale rufous. Kan-Pau-Shing, a herbalist of the tenth century, observes of the Shang-luh: "The red flower accompanies the red root and the white flower the white root" (*See* Iinuma, "Sômoku Dzusetsu," new ed., 1874, vol. vii. fol. 89, *b*; Li Shi-Chin, *loc. cit.*)

[3] "The district of Kiang-Nan is much infested by the *Ku*. On the fifth day of the fifth moon, the future keeper of the *Ku* puts together in a vessel a hundred different sorts of animals, varying in size from serpent to louse, which are left therein to mutually devour till but one remains the strongest. This he keeps and feeds in his house as the *Ku*. Whomsoever the keeper wishes to destroy the *Ku* infests in the viscera; consequently the man dies, his treasures passing over to the *Ku*-keeper's house," &c. ("Sui-shu," written seventh century, A.D., quoted in Tsiau Hwang, "Tsiau-shi-pih-shing," Brit. Mus. copy, 15316, *a*, fasc. ii. tom. v. fol. 24, *a*; Ching Tsiau, *op. cit.*, tom. xxxiii. fol. 11, *b*; *cf.* Morrison, "Dictionary of the Chinese Language," London and Macao, 1823. vol. iii. part i. p. 288.) Among the stories pertaining to the *Ku* several incidents occur parallel to those about the mandrake (*cf.* Folkard, *loc. cit.*; Li Shi-Chin, sub. "Kin-tsan"; Kitamura, Kiyû Shôran, new ed., Tôkyô, 1882, tom. viii. fol. 22). Just as are the cases with the mandrake and the Shang-luh, a herb called Lang-tang (*Scopolia* sp.?) is reputed to make men insane, yet withal to cure demoniacal possession (*cf.* Wu Ki-Siun, *op. cit.*, tom. xxiv. fol. 77, *b*; Josephus, *loc. cit.*).

So far the many analogies between the mandrake- and the Phytolacca-stories appear to militate against the probability of the independent growths, if not origins, of the folk-lores connected with the two plants.

Further, it may be worthy of notice that, while the ancient Europeans possessed a hazy knowledge of the anthropomorphous Ginseng (21), the Chinese of middle ages had an equally circuitous acquaintance with the mandrake. The fact is well evinced in the following passage of Chau Mih (1232 1308) (22): "Several thousand miles west of the Region of Moslem,[1] the land produces one substance extremely poisonous, which is shaped like man as our Ginseng is. It is called 'Yah-puh-lü,' and grows under the ground several *chang* deep [1 *chang* = 10 Chinese feet]. Should a man bruise its skin, its poison would adhere to and kill him. The only method of gathering it is this: dig around the said substance a hollow deep enough for a man's management therein; with one end of a thong tie up the substance lightly, and with other end bind round a big dog's leg. Now flog the dog; he will, striving to avoid the danger, pluck the substance from the ground, but he will die instantly. The stuff thus procured is buried under other ground, whence it is taken out a year after; then it is dried and prepared with another medicine. When man takes internally a bit of this mixed with wine, it makes him soon fall down unconscious even of cuts and chops; still there is a certain drug which, if used within three days, can recover the man. It is very likely that the celebrated Hwa To [a surgeon who flourished in the third century, A.D.] barely resorted to this drug when, as is traditionally said, he cut open his patients' bellies to cleanse viscela without harm. Presently we learn our Imperial Hospital possesses two pieces of this drug."

The readers of the above passage scarcely need my annotations that the story is obviously composed of what Josephus and Dioscorides record (23), and also that the name "Yah-puh-lü" is nothing but "Ybruh," the Arabic word for the mandrake[2] (24).

KUMAGUSU MINAKATA.

15 Blithfield Street, Kensington, W., July 16.

P.S.—In writing the present letter, I have not consulted the late Prof. Veth's exhaustive account of the mandrake-stories referred to in NATURE (vol. li. p. 573.) To my great regret it is written in Dutch, a language which is beyond the reach of my understanding. K. M.

[1] In another work by same author, "Kwei-sin-tsah-shih," quoted by Li Shi-Chin, *op. cit.*, sub. "Yah-puh-lü," this herb is said to grow in the "Region of Moslem, north of the Desert," and there it is indicated that the degraded officers of an extreme ignominy used this drug [to feign self-murder]. The Imperial "Yuen-kien-lui-han," *op. cit.*, tom. ccccxi., gives a proverb: "Eat the herb by name Yah-puh-lü; you die, still you are not dead."

[2] Fang I-Chi, the most erudite Chinese of Christian faith, referring to a work of the thirteenth (?) century, "Fang-yu-shing-loh," gives the habitat of the narcotic "Yah-puh-lü-yoh" in the country of Medina ("Tung-ya," 1643, tom. xli., fol. 8, *b*). Conventionally the latter name might be interpreted as the "Drug named Yah-puh-lü," but I am rather inclined to trace it to the name "Yabrochak" used in Palestine for the mandrake (Pickering, *loc. cit.*)

THE ECLIPSE OF THE SUN.

IF it be true that science advances through failures, the clouds which prevented the observation of the total eclipse of the sun last Sunday may be a blessing in disguise. During the past quarter of a century, several astronomers have taken up the problem of discovering a means of photographing the corona in broad daylight, but the results have not been very encouraging. In the photography of solar prominences, Prof. Hale and Dr. Deslandres have obtained distinctly valuable pictures, and, were it possible to delineate the corona with the same success on any day when the sun is shining, our knowledge of the nature of that solar appendage would increase much more rapidly than it can at present, when the only opportunities for studying it are afforded by the brief moments of totality of a solar eclipse. Perhaps last Sunday's experience will induce solar physicists to give further attention to the artificial reproduction of eclipse conditions. It is, of course, not suggested that every-day observations will make eclipse expeditions unnecessary—there will be work for astronomers during solar eclipses for a long time to come—but if it were possible to carry out systematic researches on the structure and constitution of the solar surroundings, instead of depending entirely upon the rare intervals when the photosphere is obscured, several moot points might be settled before the end of this century.

Observations of the total eclipse of Sunday last were made impossible by clouds. From all along the line of observers, the same report of foiled intentions has been received. At Vadsö, and in the neighbourhood, the sun was entirely obscured during totality, and no observations of scientific importance were obtained. The party of Russian astronomers who stationed themselves at the village of Orloffskoe, on the Amur, were equally unsuccessful in making observations. The eclipse was visible as a partial eclipse at Tokio, but at Akeshi, in the island of Yezo, where the Japanese, American, and British observers had set up their instruments, the weather was wet and the sky cloudy, and it is reported that the preparations made ended in a fiasco. It is not definitely known what happened at Esashi, where Prof. Todd and Dr. Deslandres were stationed, but little hope of success is entertained. A telegram received at Copenhagen from Bodö, Norway, states that a photographer from Flensburg has taken eleven photographs of the eclipse at Bredvik, on the Skjerstad Fiord, but more details are needed before an opinion can be expressed as to their value. News has yet to be received from the British observing party at Nova Zembla, and from the expeditions of the Russian Astronomical Society stationed at Enontekis (Finland), the mouth of the Obi, and Olekminsk, on the Lena.

Mr. Norman Lockyer has sent us the following telegram from Kiö Island, where he established a station to observe the eclipse: "Although the sun was clouded during totality, the sight was most impressive. The darkness was so great that lamps were needed. The party from H.M.S. *Volage* consisted of seventy-seven observers all trained to make notes or drawings of particular characteristics of eclipse phenomena, such as coronal structure, extent of the corona, and the colours of sky, cloud, and land and water surfaces, and to take the times of contact. The party was also provided with spectroscopes for analysing the lights of the corona and prominences, prismatic cameras for photographing the spectra of these objects, and polariscopes." With such an army of organised observers, an immense amount of valuable information would have been accumulated had the eclipse been visible. The exceptional opportunities for accurate observation offered by the presence of the Training Squadron gives astronomers reason for keen disappointment at the failure of the eclipse as an observable event; but students of science are used to the

destruction of their hopes, and the next total solar eclipse will be as eagerly looked forward to as the one just hidden from them.

An interesting description of the scene in the neighbourhood of Vadsö appeared in Tuesday's *Times*, and the following is an abridgement of it.

On Sunday morning the Varanger Fiord in the north-east of Norway presented a scene which has probably never before been equalled in a latitude of 70°. The anchorage at the port of Vadsö was crowded with men-of-war, yachts, and passenger steamers, brought together by reason of the total solar eclipse. For several days the numerous astronomers on these ships have been engaged in landing their delicate and elaborate instruments, and transporting them to the beautiful sites which here abound.

By last night the laborious preparations of the different observing parties had been completed, and they awaited with what composure they might the momentous events of the morrow. In any circumstances an Arctic summer night, where broad daylight reigns throughout, is very different from a night in a temperate region. But on this occasion there were so many interruptions, partly by the arrival of friends in the various ships, that rest was but little thought of, and indeed from two to five and even earlier a succession of boats brought hundreds of passengers from the ships to the shore.

The fence which marked out the ground occupied by the observers was guarded by bluejackets, charged with the duty of keeping at a suitable distance the groups of picturesquely-clad Finns and Lapps, who gazed with astonishment on the strangers who had travelled so far, and on the wonderful appliances they had brought with them. Many of these Arctic inhabitants were, however, sufficiently sophisticated to be provided with the traditional pieces of smoked glass with which to make their own observations.

The sun could not be seen at the moment when the moon first made contact, though almost immediately afterwards it was visible with a slight encroachment on the brilliant edge, showing that the eclipse had commenced. For nearly an hour hope and fear then alternated. Everything, of course, depended on the condition of the sky at the moment of totality, and it was hoped that some of the characteristic phenomena of a total eclipse might be presented. This hope was strengthened as the crescent sun waned thinner and thinner and still remained visible.

As the supreme moment of totality approached, the broad landscape sensibly darkened, and the fiord became more gloomy. It was as if some mighty thunder-shower was about to descend; but, alas! the clouds again thickened, and the observation of the moment of actual totality, if effective at all, could only be made by glimpses with a telescope through a very dense medium. Some observers were, of course, constrained to limit their attention to their instruments, and to the sole discharge of the duties which had been entrusted to them. But many were in the position of being able to look at the sun until the crescent of light was about to disappear, and then face round to the opposite point of the horizon. The object of this manœuvre was to permit the observer to see the impressive spectacle of the advance of the lunar shadow over the earth.

The situation at Vadsö lent itself admirably to the observation of this magnificent phenomenon. As the shadow advanced across the fiord, it enveloped the training squadron as it lay at anchor, the details of the ships' rigging disappeared from view, and their lights gleamed forth brilliantly. Still the shadow pressed on with its majestic speed of a mile in every couple of seconds. It moved as swiftly as a cannon-ball until it reached the observers at Vadsö, and then announced to them in the most impressive manner that the supreme moment of their visit had arrived, and that totality was complete.

The darkness that then buried Vadsö and its numerous observers lasted for a minute and forty seconds. The unwonted spectacle hushed every one to silence. A few startled birds hurried past the camp, and amid the canopy of cloud which covered the heavens at least one observer descried a star. But, though all the visitors felt that the magnificent phenomena were worthy of being remembered as a life-long experience, yet it is none the less true that, from a scientific point of view, the result of all the labours at Vadsö was hardly anything.

The object of the astronomers, who erected at such vast pains great photographic instruments, was to depict the corona and to analyse with spectroscopes the light which it dispenses. It is true that during the time of totality they exposed their plates in accordance with the careful drill and organisation which were indispensable if full advantage was to be taken of the brief period. But, unfortunately, during the time of totality the clouds were obdurate, and nothing could be seen. The innumerable telescopes directed to the sun showed no more than the same instruments would have done if they remained still covered.

The 100 seconds fled, marked only by the mechanical precision of the officer who counted them aloud. The astronomers might safely spare glances to the interesting view over land and sea. The light around them was not greater than that during a full moon, but in the distance mountain-tops could be descried which were not in the shadow and were shining brilliantly.

At last the darkness lifted, and the manner in which the light returned was almost startling in its suddenness. It was not that the sun became visible—this, indeed, did not at first happen—but when the moon had passed by, and when totality was over, the sun illumined the clouds, and this gave again the usual light of cloudy day when the orb itself is invisible. A few seconds later a glimpse was afforded of the crescent form of the sun, and then the clouds closed in once more, and did not withdraw until long after the moon had passed away from the disc.

THE PHYSICAL LABORATORY AT LEIDEN (HOLLAND).

WHEN a few years ago it appeared advisable to Prof Kamerlingh Onnes, the Director of the Physical Laboratory at the University of Leiden, to start the issue of a periodical paper which would contain a regular account of the research work that was going on in his laboratory, he decided upon the English language as being for various reasons the most suitable for the purpose. The "Communications from the Physical Laboratory at the University of Leiden" consist, as a rule, of more or less happy translations of contributions by Prof. Onnes and his pupils to the *Proceedings* of the "Koninklijke Akademie" of Amsterdam. They give short accounts of the researches that are carried out, and contain theoretical notes, as a rule, in direct connection with the experimental work. The full accounts of the investigations are mostly to be found elsewhere in various French, German or English periodicals.[1] No. 23 of the series appeared lately, and the whole set, containing everything that has been done in the laboratory since 1885, is now complete.

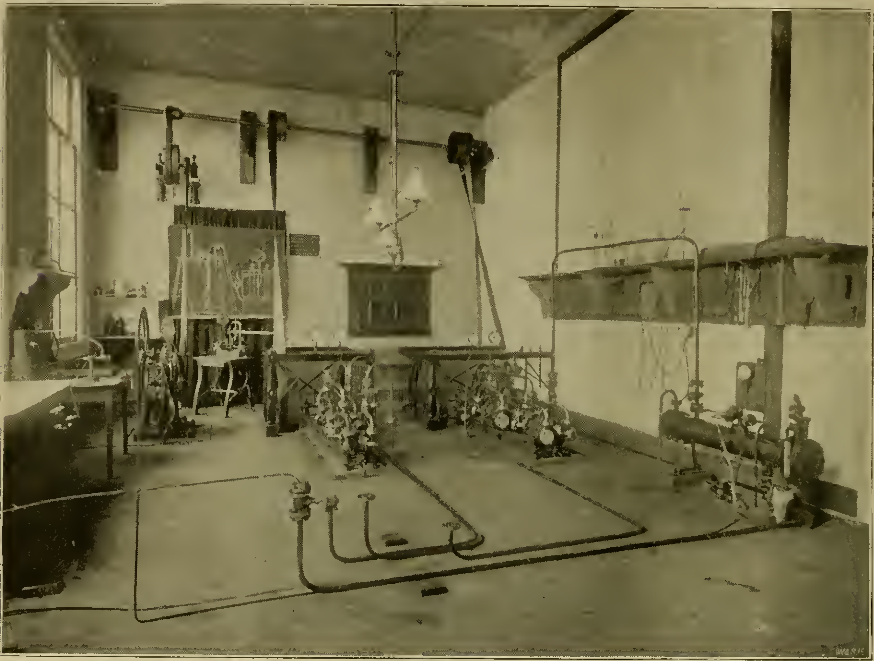
The most important characteristic which distinguishes the Leiden laboratory from most of its contemporaries is its installation for high-pressure and low temperature work. There are probably only one or two more places where an installation of this kind is permanently joined to a well-provided physical laboratory. Nos. 14 and 23 (especially the former) give a general idea of its gradual development and present arrangement.

Ever since 1883 Prof. Onnes has been working at this department. His object was in the first place to develop and improve the methods introduced by Cailletet, Pictet, Wroblewski, Olszewski, and to prepare larger quantities of liquid oxygen than before, so as to be able to decant it and use it as a cooling agent for experiments, especially on the liquefaction of hydrogen. The same object was, during the same years, striven after by Pictet, Olszewski and, in this country, by Dewar. Owing to want of sufficient funds and personal assistance, the work progressed very slowly, and it was not till June 1892, that a small quantity of liquid oxygen was decanted, while in December 1893 half a litre was obtained. It is interesting to notice how entirely independent the Leiden work is from the others. In the first place, Prof. Onnes uses Pictet's cycle method, while Olszewski developed the method used by Wroblewski in conjunction with himself. Instead of sulphurous acid, used by Pictet, he introduced methylchloride in the first cycle (a suggestion of Cailletet's), while ethylene remained

[1] *Archives Néerlandaises, Wiedemann's Annalen, Beiblätter, Zeitschrift für Physikalische Chemie, Philosophical Magazine.*

the second substance. Both substances are in continual circulation in metallic, self-contained cycles, which are worked by two Pictet conjugated pumps. While Olszewski introduced a steel cyclinder in which to liquefy oxygen, Prof. Onnes devised an "ethylene boiling flask" in which oxygen (or air) is condensed in a copper spiral. The glass apparatus into which the oxygen is poured is of original construction, and especially adapted for experimental work in oxygen (or air) baths of $\frac{1}{4}$ to $\frac{1}{2}$ litre.

Sometimes instead of the methylchloride cycle solid carbonic acid is used. Experiments on the insertion of a methane cycle between the ethylene and oxygen, with the ultimate object of condensing hydrogen, are still being carried on. Oxygen and air are taken from high-pressure cylinders, into which they are compressed either by a Brotherhood compressor (as used in launching torpedos) into a kind of model "cryogenic laboratory," as Prof. Onnes calls his creation, with emphasis on both cryogenic and laboratory. Occasional comparisons with other cryogenic installations illustrate this vividly. Dewar works with quantities of ethylene up to "a hundredweight" (40 kg.), while Prof. Onnes requires 1·5 kg., by aid of which $\frac{1}{4}$ to $\frac{1}{2}$ litre of oxygen is kept liquid. Pictet estimates the power required for experiments with liquid air at from 30 to 40 h.p., while in the Leiden laboratory only six or eight are required, even in exceptional cases. Olszewski gives his power as 1–3 h.p., but it must not be forgotten that his system is not a continuous one, and that the largest quantity which his apparatus in its enlarged form yields is 200 cc., only $\frac{1}{3}$ of which gets into his boiling-glass. His experiments require a correspondingly smaller quantity of ethylene (1 kg.).



View of the cryogenic department in 1887, showing the compressors destined for the chlormethyl, ethylene, and oxygen cycle. At the right the chlormethyl condenser.

or by a much less powerful, but in other respects highly superior Cailletet compressor. This compressor as modified, almost re-designed by Prof. Onnes, is a most desirable laboratory apparatus where high-pressure work with pure gases is being done. The chief modification is that the mercury column works in a steel U-tube, so that the piston with its lubricant (glycerine) is on one side above it, and the valves, &c., on the other. This compressor may be fully depended upon; the gases remain just as pure as they were, and may be compressed to 100 atmospheres without loss. (A full description of this compressor may shortly be expected.)

It is worth noticing that the greatest possible care is taken (and had to be taken) in the way of safety and of economy; these circumstances make the department

It need hardly be said that these low figures have only been arrived at by a slow process of trial and gradual improvement, and one cannot but admire the perseverance and skill which the development of this system reveals.

Now that the cryogenic department is so far completed that baths of liquid oxygen and air may be readily prepared, no doubt the co-operation with the rest of the laboratory will become more regular and fruitful. Even now, in reading through the "Communications," we come repeatedly across instances in which the high-pressure and low temperature appliances have given invaluable help.

At one time, for instance, pure oxygen was required for experiments on the magnetic rotation in gases at high pressure (Nos. 7, 15). Commercial oxygen being too

impure for the purpose, the preparation of a cubic metre of oxygen was undertaken. The gas was prepared by electrolysis, conducted through purifying apparatus, and compressed into a steel cyclinder of 10 litres capacity, at a pressure of 100 atmospheres by the mercury compressor. The gas in the cylinder appeared to contain nearly 99 per cent. of oxygen. How many laboratories exist in which such a thing could be performed?

As to low temperatures, in No. 6 we notice the measurement of the capillary elevation of ether at -102° in boiling ethylene; in No. 18, of the same magnitude for carbonic acid and nitrous oxide at -24° in boiling methylchloride. Nos. 4, 16, 18 contain the description of a method for purifying gases by condensation and fractional distillation at low temperature, in a bath of ethylene or in solid carbonic acid, the gases purified being carbonic acid, methylchloride, nitrous oxide, and ethane. Finally, we may note the measurement of the viscosity of methylchloride at -30° in cooled alcohol.

The different investigations hitherto carried out may be arranged under the following headings.

I. Cryogenic department: condensation of methane, isothermals of hydrogen at low temperatures, &c. (Nos. 14, 23.)

II. Investigations regarding critical points and condensation of mixtures and of pure substances. (Dr. Kuenen. Nos. 4, 7, 8, 11, 13, 16, 17.)

III. Measurements on the capillarity of ether, carbonic acid, nitrous oxide, &c. (Drs. de Vries and Verschaffelt. Nos. 6, 18.)

IV. Measurements on the viscosity of methylchloride in connection with the laws of corresponding states of matter. (Drs. Stoel and de Haas. Nos. 2, 12.)

V. Series of experiments on Kerr's magneto-optical phenomenon, &c. (Drs. Sissingh, Wind and Zeeman. Nos. 1, 3, 5, 8, 9, 10, 15, 20.)

VI. Some experiments regarding Hall's phenomenon in bismuth. (Dr. Lebret. Nos. 15, 19.)

VII. On Hertz-waves in water and in electrolytes. (Dr. Zeeman, partly in conjunction with Prof. Cohn, Strassburg. Nos. 21, 22.)

VIII. Observations on the dispersion of magnetic rotation in gases. (Dr. Siertsema. Nos. 7, 15.)

The scope of this article does not allow of a further description or discussion of any of the above investigations. One instance will show the scale on which the experiments are carried on, if deemed necessary. For the observations mentioned under VIII., two coils were constructed, each of 1 metre length and with 3600 turns of 6 mm. wire, the joint resistance of the coils in series being 1 ohm, and the current carried 70 amperes.

Besides a dynamo there are two or three sets of accumulators, which make it possible to work simultaneously at two or three investigations for which strong currents and electric lamps are required. In short, the place is rich in apparatus of all kinds, and possesses numerous appliances; so much so, that one would rank it amongst the best provided (and, one may add, most productive) research laboratories. It is worth observing, that in Holland private munificence is hardly ever directed towards scientific work, and that the whole of this laboratory, as of all the others in the three Government Universities—Leiden, Utrecht, Groningen—are kept up from the public purse. It is only recently that, under the strain of the competition between the Universities, private societies have been founded to promote University work, where the Government shows itself unwilling or unable to provide the necessary means.

Those to whom these "Communications" are unknown, and who are desirous of becoming more intimately acquainted with their contents, have only to apply for copies to receive them. Prof. Onnes will, moreover, be very glad if physicists, touring in Holland, would alight at the famous University town, and in their programme include a visit to his laboratory.

THE GREAT RIFT VALLEY.[1]

IT is but rarely that a narrative of travel, however interesting it may be, and however exciting the adventures of the author may have proved, has as much attraction for naturalists and geologists as the present volume possesses. Dr. Gregory has shown himself a thoroughly competent explorer, for he succeeded in reaching the glaciers close to the summit of Mount Kenya, the highest peak of British East Africa, a task in which several previous travellers had failed; and he also examined a considerable length of the extraordinary tract that gives its name to the book before us. This, too, was accomplished with a much smaller caravan than was regarded by experienced men as necessary for safety; in face of difficulties, due to the proclivities of the natives and to scarcity of food, that would have daunted many men; in spite of the utter failure of the expedition to which the author was originally attached; and, above all, despite severe attacks of malarial fever and dysentery. "The Great Rift Valley," apart from its scientific interest, gives a very interesting account of an adventurous exploit, carried out with courage and firmness, and, at the same time, with kindly treatment of the natives employed and encountered.

It is, however, not as a record of exploration alone that this book needs notice. Explorers equal to Dr. Gregory in courage and tact, and perhaps superior to him in the power of resisting malarial influences, have made their way through many of the forests and deserts of Africa, and have told some of the secrets of the Dark Continent to an appreciative audience; but very few of those who returned to tell the tale of their adventures possessed the scientific training that gives an especial value to Dr. Gregory's account of his travels. In this respect the author of the present work is singularly qualified. In the era of specialisation in science that we have now entered upon, it is becoming rare to find a geologist who knows anything of zoology or botany, or a zoologist or botanist who can tell schist from shale or sandstone from granite; whilst it appears to be rapidly becoming a point almost of honour with the geologists, zoologists, and botanists of the British Islands to regard palæontology as an inferior science. It is therefore noteworthy that Dr. Gregory, who is a palæontologist, should have brought back from Eastern Africa a mass of observations that could not have been accumulated by a geologist ignorant of biology, nor by a zoologist or botanist unacquainted with geology.

Briefly the history of the journey described is this. In November 1892, Dr. Gregory received leave of absence from the Trustees of the British Museum to enable him to join an expedition to Lake Rudolf. From various causes this expedition was a failure. After the dispersal of its members, Dr. Gregory went on to Mombasa, where he engaged a small party of porters, and in March 1893 started for Lake Baringo and Mount Kenya, and succeeded in reaching both. The journey occupied five months, and the expedition returned to Mombasa in August.

The arrangement of the present work is the following. After an introduction, giving a general account of previous exploration, and of the geology of the area as known before the author's visit, the first three chapters relate his experience with the abortive expedition which started from Lamu to explore Lake Rudolf and the regions between that lake and the Red Sea, but never got beyond the lower reaches of the Tana River; then eight chapters contain a description of the journey to Baringo and Kenya; and the third part of the book, comprising

[1] "The Great Rift Valley: being the Narrative of a Journey to Mount Kenya and Lake Baringo, with some Account of the Geology, Natural History, Anthropology, and Future Prospects of British East Africa." By J. W. Gregory, D.Sc., F.G.S., F.R.G.S., F.Z.S., of the British Museum (Natural History). (London: John Murray, 1896.)

seven chapters and three appendices, affords a general summary of the scientific results.

The "Great Rift Valley," of which the characters were first indicated by Suess, is a fissure in the earth's surface into which, or into portions of which, a strip of the surface itself has been let down by parallel faults. The cliffs formed by the faults have not been removed by denudation, and the necessary inference is that the dislocation—partially, at all events—is of small geological antiquity. The great fissure itself is regarded as similar in character to certain lines, resembling cracks, that have been observed on the moon's surface; it has been traced at intervals from the valley of the Zambesi to Lake Rudolf, and it is supposed to be connected through the trough of the Red Sea with the depression containing the Jordan Valley and the Dead Sea in Palestine. From Lake Rudolf a branch rift appears to diverge to the west, and to lead through Lakes Albert and Albert Edward to Tanganyika; whilst south of Lake Rudolf the eastern branch, our knowledge of which has been materially increased by Dr. Gregory's examination, contains several smaller lakes—Baringo and Naivasha, amongst others—and probably terminates to the southward in Lake Nyassa. Altogether this wonderful north and south trough is regarded as having a length of 4000 miles, and is said to contain thirty lakes, of which only one has an outlet to the sea. Evidently only the eastern branch of the rift is referred to, fo :three large lakes in the western branch—the Lakes Albert, Albert Edward, and Tanganyika are drained by the Nile or the Congo.

The principal additions to our knowledge of the "Great Rift Valley" are two in number. Dr. Gregory has shown, apparently beyond any chance of error, that the portion of the valley examined by him—fifty to seventy miles on each side of the equator, or about 120 miles in all—is actually let down by faults on each side. He has also shown that great changes in elevation must have occurred throughout the area in comparatively recent geological times, and that one of these led to the formation of a large lake, of which traces are left in the form of terraces on some of the scarps that bound the Rift Valley. To the ancient lake Dr. Gregory applies the name of Lake Suess; and, if a name is required, no more appropriate one could be devised.

The discoveries on Kenya were even more important than those in the Rift Valley, for not only did Dr. Gregory find glaciers, but he met with clear evidence that these glaciers formerly descended more than 5000 feet lower down the mountain than they now do. Reasons are given—one of the most important being the absence of any similar evidence on Kilimanjaro—for doubting whether the former extension of glacial action on Kenya was due to a general refrigeration of the earth's surface in the glacial epoch, and it is inferred that Kenya and the surrounding area have undergone depression since the period of maximum glaciation on the mountain. This may be the case, but it leaves the great difficulty of the whole question unexplained; we have still to account for the isolated occurrence of temperate plants, both of northern and southern types, on all the Central African mountains.

A considerable mass of interesting details on the geology of the country lying between the coast and the Rift Valley is given, and incidentally, with reference to the great lava plains traversed, their origin is discussed and a theory put forward to account for the phenomena.

FIG. 1.—The Eastern Wall of the Rift Valley, with the Terraces of Lake Suess.

It may, however, be doubted whether this theory, which its author terms that of plateau eruption, is really different from the explanation of the so-called fissure eruptions given in Sir A. Geikie's text-book.

It is when we pass from the purely geological chapters to those portions of the work that refer to the East African fauna and flora, and to the descriptions of the various tribes who inhabit the country, that we come to what will probably prove to many readers the most attractive portion of Dr. Gregory's work. The pages relating to the present and past distribution of life teem with original suggestions, and many of the observations made on the journey are highly novel and interesting. Amongst these are some curious cases of mimicry, especially that represented in the frontispiece to the volume, in which a group of hemipterous insects, red and green, presents an astonishing similarity to a flower-spike. Remarkable examples are given of the disappearance of wild animals, such as buffaloes and giraffes, throughout a very large tract of country, in consequence of disease; whilst observed instances of the destruction of great numbers by drought, and the accumulation of their skeletons around isolated water-holes, are suggested as perhaps accounting for some of the enormous masses of mammalian bones that are found imbedded in particular strata. It is not necessary to agree with suggestions of this kind in order to recognise their value; and unquestionably under the conditions pointed out, if the bones are, soon after the death of the animal, enclosed in silt or gravel, they may be preserved. Bones exposed on the surface, however, especially in the tropics, decay and break up with great rapidity, and the accumulations of fossil bones occasionally found are more probably due to carcases, carried down by a river flood, having collected in a backwater or on a sandbank.

One example of a suggestion of the author's, peculiarly illustrative of his double range of investigation, as geologist and as biologist, may here be noticed. It has long been known—we are indebted to Dr. Günther for the original facts—that the fresh water fish-fauna of the Jordan and Sea of Galilee resembles in certain peculiarities, such as the presence of the genus *Hemichromis*, that of the Central African lakes more than that of Northern Africa and of the lower Nile basin. Dr. Gregory shows the possibility of the Red Sea depression having once been the valley of a river flowing into the Indian Ocean, and receiving near its mouth a tributary from the large lakes that formerly existed in the Rift Valley, and that may have occupied a considerable portion of what is now the upper Nile basin. This is of course, as is fully admitted, hypothesis, but it is supported by a very curious mass of data, and it explains the difficulties better than any other suggestion hitherto put forward.

One characteristic of Dr. Gregory is a taste for naming various things, past and present. In many cases this is useful, as when he maps and names the ridges and valleys of Mount Kenya. It may also be of service to have a name, like Lake Suess, for an ancient sheet of water of which evident traces remain; but it is somewhat questionable whether there is any advantage in calling the hypothetical stream, that may at some past time have traversed the Red Sea, the Erythraean river. In one case the author of the "Great Rift Valley" appears, in the application ot names, to have departed from the usual practice. Geologists have generally given local names to rock-systems and their divisions, and have referred them, so far as they were able, to the geological periods, or divisions of geological time, recognised in Europe. To judge by the table at p. 235, certain names—Naivashan, Laikipian, &c. —are given to divisions of geological time rather than to rock-masses, and it is fairly open to grave

Fig. 2.—Two Wa-pokomo of the Tana.

doubt whether this is an improvement on the usual practice.

The chapters on the flora of East Africa, and those on the Zanzibari and other natives of the country, contain a large amount of information, and are thoroughly readable. The same may be said of the concluding chapter on the national movements and future prospects of British East Africa. The whole book is clearly and well written and liberally illustrated, and the author, who quotes—and quotes appositely—not only Shakespeare, Byron and Göethe, but also Carlyle, Buckle, and Rudyard Kipling, has evidently gleaned widely in literary as well as in scientific fields. W. T. BLANFORD.

THE MEETING OF THE INTERNATIONAL COMMITTEE OF THE CARTE DU CIEL.[1]

AT the fourth meeting of the International Committee of the Carte du Ciel, which took place at the Paris Observatory in May, under the presidency of M. Tisserand, the following members were present: MM. Anguiano, Bailland, Bakhuyzen, Christie, Donner, Duner, Gill, Henry (Paul), Henry (Prosper), Loewy, Rayet, Ricco, Trépied, Turner, Viniegra. There were also present at the invitation of the Permanent Committee, MM. Abney, Backlund, Bouguet de la Grye, Callandreau, Common, Cornu, Downing, Fabre, Faye, Gautier (P.), Jacoby, Knobel, Laïs, Laussedat, Newcomb, Perrotin, Scheiner, Stephan, Wolf.

Of the eighteen observatories associated for the production of the Carte du Ciel, thirteen were represented. The directors of the five other observatories, MM. Russell (Sydney), Baracchi (Melbourne), Obrecht (Santiago), Cruls (Rio Janeiro), Beuf (La Plata), were prevented from attending by great distance or by professional duties.

The following officers were elected: President, M. Tisserand; Vice-Presidents, MM. Bakhuyzen and Gill; Secretaries, MM. Donner and Trépied.

The following resolutions were adopted:—

I.—*Photographic Catalogue.*

1. The Committee is of opinion that the probable error of the value of the rectilinear coordinates measured on the plates should be reduced to the smallest possible limits, and that the measurements must be directed in such a way that this probable error shall never exceed 0″·20.

2. (*a*) The Committee thinks it necessary to publish the rectilinear coordinates of the photographed stars as soon as possible.

(*b*) It is desirable that this publication should include the necessary information for the conversion of the results into equatorial coordinates.

(*c*) The Committee desires that a provisional catalogue of right ascensions and declinations should be published by those observatories which have sufficient funds at their disposal.

3. Each observatory will be at liberty to choose the positions of the comparison stars in the catalogues which seem to them most suitable. For the calculation of the constants of a plate, a minimum of ten comparison stars should be adopted if possible. The adopted positions of these comparison stars will be published.

4. The question of determining whether, for the reduction of the stars to 1900, it would be advisable to adopt a uniform system of constants for the observatories, will be the subject of a subsequent discussion.

5. The Committee recommends the adoption of a uniform size of publication for all the observatories; the size should be that of the volumes of the Catalogue of the Paris Observatory.

[1] Abridged from the *Bulletin Astronomique*, July 1896.

6. The observatories will be at liberty to determine the photographic magnitudes, either by measurements or by estimation. The only condition which the Committee thinks it necessary to impose, is that the system of photographic magnitudes on which the measures or estimations depend, should allow of a precise definition, so that the different scales used in the different observatories can be reduced to a common system.

II.—*The Photographic Chart.*

7. Every observatory will be provided with a scale of density, which will be printed on the plates at the same time as the *réseau*, and which will permit the determination of the sensibility of each plate for luminous sources of different intensities.

Captain Abney is charged by the Committee with the construction of the scales.

8. For the construction of the chart, the second series of negatives (that is to say, those of which the centres have odd numbers for their declinations) will be made in three exposures, each lasting thirty minutes. This time of exposure may, of course, be reduced if an increase of the sensibility of the photographic plates be secured.

9. The Committee allows photogravure on copper as a means of reproducing the chart. The negatives to be exposed three times, and enlarged to twice the original size.

10. The observatories will make two positives on glass by contact, one of which will be placed in the Pavillon de Breteuil, the headquarters of the International Bureau of Weights and Measures.

11. The Committee defers till the next meeting the examination of the measures which it may be necessary to take with the object of assisting those observatories which may anticipate a difficulty in completing their programme.

The meetings of the Committee were marked with the greatest cordiality, and with the desire to carry to the end the great work undertaken in common; the decisions, prepared by special sub-Committees, were passed unanimously by the members present.

The Conference was followed by a soirée on Saturday, May 16, and by a dinner given the next day (Sunday, May 17), in the large gallery of the Observatory, at which the following were present: MM. Rambaud, Minister of Public Instruction; Bertrand and Berthelot, Permanent Secretaries of the Academy of Sciences; Cornu and Chatin, President and Vice-President of the Academy; the members of the Committee, and numerous visitors belonging to the Academy, the Bureau des Longitudes, the Council of the Observatory, and the *personnel* of the establishment. Prof. Backlund, Dr. Downing, and Prof. Newcomb, members of the Conference on fundamental stars, were also present.

NOTES.

LIEUTENANT DE GERLACHE announces that the Belgian Antarctic Expedition he has been organising for some time past will not be sufficiently advanced to start before next year.

M. EUGÈNE TISSERAND will shortly retire from the post of Director-General of Agriculture in France, after forty-six years of public service.

EXTREMELY hot weather is reported from North America. In New York, on Tuesday, the shade temperature reached 97° F. As many as 226 deaths are recorded as being directly due to this abnormally high temperature. In Chicago there were fifty-one deaths on Monday, and twenty-five on Tuesday. Hundreds of dead horses are said to be lying in the streets. The thermometer registered 96° F. at Ottawa.

THE deaths are announced of Dr. Kanitz, Professor of Botany in Klausenberg University, and Dr. Simony, formerly Professor of Physiography at Vienna.

OWING to a doubt having arisen as to whether the publication of *Climate and Health* was authorised by the Act appropriating to the U.S. Department of Agriculture the grant for the fiscal year ending June 30, 1897, that valuable repertory of statistical and other information relating to climatology and its connection with hygiene, has had to be discontinued. The special papers intended for it will be published in separate bulletins.

THE opticians of Pennsylvania are endeavouring to form a State organisation, having for its objects, first, the elevation and advancement of the profession and the mutual intercourse and benefit of its members; second, to encourage opticians to perfect themselves in the study of optics and the scientific adaptation of lenses in correcting errors of refraction; and, third, to discourage the haphazard and indiscriminate sale of spectacles by irresponsible and ignorant persons. British opticians might with advantage follow the lead of their Transatlantic brethren.

THE fifteenth Congress of the Sanitary Institute will be held at Newcastle-upon-Tyne, from September 2 to September 9. An inaugural address will be delivered by Earl Percy, and lectures will be given by Dr. A. Wynter Blyth and Sir Charles A. Cameron. The Sections and their Presidents are: (1) Sanitary Science and Preventive Medicine; President, Prof. W. H. Corfield. (2) Engineering and Architecture; President, Sir Andrew Noble. (3) Chemistry, Meteorology, and Geology; President, W. H. Dines. There will be conferences of port sanitary authorities, medical officers of health, municipal and county engineers, sanitary inspectors, and on domestic hygiene. Excursions and visits to places of interest will be made during the Congress, and particulars with reference to them will shortly be made known. The Health Exhibition, held in connection with the Congress, will be opened by the Duke of Cambridge.

THE summer meeting of the Institution of Junior Engineers will be opened on Saturday at Edinburgh. After visiting the Forth Bridge and a number of industrial works, the members will leave on Tuesday next for Glasgow, where many places of engineering interest await their inspection. In the afternoon of the same day the members will be received in the Municipal Buildings by the Lord Provost and the Corporation, afterwards being entertained to an excursion to visit one of the new reservoirs of the Glasgow Corporation Water Works. On Wednesday there will be an excursion to Dumbarton, and a reception by the Provost and Town Council. An excursion will take place on Thursday; and on Friday various works will be open for visiting, the selection being left with the members. In the evening of Friday, the Institution's summer dinner will be held at the Alexandra Hotel, Glasgow, the President, Mr. Archibald Denny, in the chair, and Lord Kelvin the guest of the evening.

IN the *Bulletin* of the University of Wisconsin (Engineering Series, vol. i. No. 9), Mr. G. A. Gerdtzen discusses in a very complete manner the relative advantages of gas, steam, and electricity for the supply of heat, light, and power for domestic purposes. Electricity gives a perfect solution of the problem considered apart from expense, but practically it is out of the question for heating purposes. Although most of the European work on the subject is mentioned and discussed, the chief interest of the paper lies in the details of American practice. Stress is laid by the author on the altered conditions due to the extensive introduction of incandescent gas-burners.

THE following are among the exhibitions at present open, or which will be opened in various parts of the world before the end of the century. 1896: Odessa, Industrial and Fine Arts; Prague, International Pharmaceutical; Cannes, International; Rouen, National and Colonial; Geneva, National; Berlin, Industrial; Kiel, Maritime and Fisheries; Mexico, International; Exhibition at Para; Exhibition at Johannesburg; New York, Electric; Barcelona, Industrial Arts; Denver (Colorado), International Mining and Industrial; Vienna, Agricultural Machinery; Nijni-Novgorod, National; Innsbruck, Hygienic; Lyons, Exhibition of Natural Hygiene; London, Motors and Automatic Carriages. 1897: Brussels, International; Hamburg, International Horticultural; Rio Janeiro Exhibition; Guatemala, Central American; Exhibition at Brisbane; Exhibition at Stockholm; Montreal, International; Nashville (Tennessee), International Industrial and Fine Arts. 1898: Amsterdam, Universal; Exhibition at St. Paul, Brazil; Exhibition at Turin. 1899: Exhibition at Adelaide. 1900: Universal Exhibition at Paris.

BY the death of Mr. H. J. Slack, at the advanced age of seventy-eight, science has lost one of its most keen journalistic champions. In years when headway had to be made against prejudice and even antagonism, his enthusiasm inspired many younger workers, and he saw in the spread of science one of the great factors of social progress. For many years he edited the *Intellectual Observer*, which passed later into the *Student*, a journal which to him was largely a labour of love, and which, by its attractive form, had a wide educational value. His own researches were mostly in microscopy, and he was successively Secretary and President of the Royal Microscopical Society. Forty-six papers are ascribed to his name in the Royal Society's Scientific Catalogue; and his work entitled "The Marvels of Pond Life," passed through three editions between 1861 and 1878. In 1879, as President of the National Sunday League, Mr. Slack organised popular lectures for Sunday evenings in London, and did much to inaugurate that movement in furtherance of a rational Sunday, which has now gone so far as to receive parliamentary recognition. He was one of those who combined devotion to science with a broad sense of public needs; for him, science had its duties as well as its rights; and few can have come in contact with him without being the better for his cheerful and unflagging zeal in the causes which he had at heart. He was born on October 23, 1818, and died in his house at Forest Row, Sussex, on June 16, 1896.

A BILL to legalise the use o. weights and measures of the metric system in this country was read for the first time in the House of Commons on July 30. The Bill is as follows:—"I. (1) Notwithstanding anything in the Weights and Measures Act, 1878, the use of a weight or measure of the metric system in trade shall be lawful, and nothing in section nineteen of that Act shall make void any contract, bargain, sale, or dealing by reason only of its being made or had according to weights or measures of the metric system. (2) A person using or having in his possession a weight or measure of the metric system shall not by reason thereof be liable to any fine. (3) For the Third Schedule to the Weights and Measures Act, 1878, shall be substituted the Schedule to this Act. II. Section thirty-eight of the Weights and Measures Act, 1878, is hereby repealed, and the Board of Trade shall verify copies of metric standards in the same manner as if they were copies of Board of Trade standards, and the provisions of that Act relating to the verification of local standards shall apply accordingly. III. In section forty of the Weights and Measures Act, 1878, the expression 'local standards of weights and measures' shall include local metric standards and the provisions of that Act relating to local standards shall apply accordingly." The Schedule to the Bill gives a series of equivalents of metric and imperial weights and measures. The Bill will not be proceeded with this Session.

A return has been presented to Parliament showing the number of licensed experiments performed on living animals during the year 1895. The total number of persons holding licences was 213, but of these 65 performed no experiments. Tables are given which afford evidence (1) that the licences and certificates have been granted and allowed only upon the recommendations of persons of high scientific standing; (2) that the licensees are persons who, by their training and education, are fitted to undertake experimental work and to profit by it; and (3) that all experimental work has been conducted in suitable places. The total number of experiments performed in 1895 was 4679. In 1560 of the experiments performed the animal suffered no pain, because complete anæsthesia was maintained from before the commencement of the experiment until the animal was killed; 2358 of the experiments were practically always of the nature of hypodermic injections or inoculations. In 761 experiments the animal was anæsthetised during the operation, but was allowed to recover. These operations, in order to insure success, are necessarily done with as much care as are similar operations upon the human subject, and, the wounds being dressed antiseptically, no pain results during the healing process. The large number of inoculation experiments is, to a great extent, attributable to investigations connected with the production of diphtheria-antitoxins and analogous bodies. More than half of the experiments under Certificate B have been inoculations made (under anæsthetics upon rodents) with the object of diagnosing rabies, the public having largely acted upon the advice printed upon the back of dog licences, which is to the following effect: "If a dog suspected of being rabid is killed after it has bitten any person or animal, a veterinary surgeon should be requested to forward the spinal cord to the Brown Institution, Wandsworth-road (or some other licensed institution) in order that it may be ascertained with certainty whether the animal was suffering from rabies."

Prof. John Milne, writing from his observing station in the Isle of Wight in reference to the long series of earth disturbances commencing on June 29 in Cyprus (see Nature, August 6, p. 325), says that he also has recorded a long series of movements commencing on that date. Two alarming and severe shocks in Cyprus, in G.M.T., commenced on June 29 at *about* 8h. 48m. os., and July 2 at *about* 18h. 13m. os. The Isle of Wight records commence on the above dates at 9h. 02m. 26s. and 18h. 51m. 29s.

Prof. Dr. A. Gerland, in the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin*, gives an account of the earthquake in South-western Germany on January 22, 1896. The disturbance was in many ways remarkable, extending as it did over an area of about 40,000 square kilometres; and it seems to have had its origin at a considerable depth below the surface, as the recorded times of its occurrence are nearly identical over the whole region affected. The disturbance lasted on an average about five seconds, and was apparently of the nature of a sudden shock in an east to west or west to east direction, although in Strassburg and Stuttgart it seems to have been vertical; affording an excellent illustration of the fact, pointed out by Prof. Schmidt, that the direction of displacement is not necessarily connected with the direction of propagation of the disturbance. A remarkable feature of the disturbed region is the occurrence of isolated areas which remained unaffected; this is especially the case in the Jura, Le Locle and La Chaux le Fonds being the only stations reporting even a slight shock.

The *Bollettino della Società Geografica Italiana* contains a note on some observations recently made by Dr. S. Angelini on the colour and transparency of the waters of the lagoon at Venice and of the Gulf of Gaeta. The depths at which white, green, red and blue discs, each 50 cm. in diameter, ceased to be visible from the surface, were measured with the following results:—

		White.	Green.	Red.	Blue.
Lagoon	Metres	1·98	1·85	1·80	1·50
Gulf of Gaeta	,,	8·50	7·80	7·00	6·00

The ratios of these numbers indicate a somewhat greater relative transparency in the waters of the lagoon for red and blue rays than for white or red.

Dr. A. Lindenkohl contributes to *Science* an abstract of a report on the work of American surveying vessels in the Gulf of Mexico and the region of the Gulf Stream during the last twenty years. The full memoir is to be published in the annual "Report of the U.S. Coast and Geodetic Survey" for 1895, and, amongst other important matter, includes a discussion of the sources from which the Gulf Stream derives its waters. It appears that the Gulf of Mexico supplies only a very small part of the whole, the currents entering and leaving it being inconsiderable both in volume and velocity.

Herr Friedrich Benesch contributes to the *Mittheilungen der K.K. Geographischen Gesellschaft in Wien* a short description of Pauliny's new method of drawing relief maps, which he says is a great advance on any method now in use, both in respect of accuracy and of ease in execution. The map is in effect a closely-contoured map, printed on silver-grey paper, the contour lines being white where illuminated by a source of light supposed to be 45° above the western horizon, and black elsewhere. Level plateaus and slightly sloping areas are thus represented by the natural grey colour of the paper; steep declivities towards the west are lightened by the closely drawn white lines, and towards the east correspondingly darkened by the black lines, the departure from the normal grey being greater the closer the lines, *i.e.* the steeper the slope. The method has the merit of giving a clear idea of *steepness* derived from the contour lines themselves; and while it does not demand the high standard of skill necessary in Lehmann's method of hachuring, the confusion produced by the shadows in some modern maps, where the illumination is supposed to come from the horizon, is avoided. Maps illustrating Herr Pauliny's method are to be published in Vienna in the course of the summer.

In the *Atti dei Lincei*, Dr. Vittorio Abelli describes a remarkable case which occurred in the course of a scientific expedition on the slopes of Monte Rosa. At an altitude of 4560 metres, a member of the party, twenty-two years of age, was suddenly attacked with pulmonitis, and subsequently completely recovered from the disease. This led Dr. Desiderio Kuthy, of Budapest, to carry on a series of experiments on the action of rarefied air on the *Diplococcus* of pulmonitis, and also on the *Pneumococcus* of Fraenkel. Two conclusions were drawn from these investigations: firstly, that rabbits after being inoculated with this *Pneumococcus* die more rapidly when they are surrounded by air at the reduced pressure corresponding to that on Monte Rosa; secondly, that this occurs although the *Pneumococcus* is less virulent when it is developed in rarefied air. In the case of the youth Ramella, Dr. Kuthy considers that the infection was mitigated in consequence of the attenuation of the *Pneumococcus* arising from the rarefaction of the air, but the same circumstance caused the attack to be more violent in spite of the mildness of the infection.

In the *Nuovo Cimento* for June, Dr. A. Fontana describes a new form of slide-rule designed for the purpose of shortening the calculation of the corrections which have to be applied when a body is weighed in air, and its weight *in vacuo* is required. The device bids fair to prove very useful in physical laboratories where weighings are constantly being made.

AT the conclusion of a lecture on the transformation of the energy of carbon into other available forms, recently delivered before the Franklin Institute by Mr. C. J. Reed, the Jacques cell, described in a note in these columns on July 30 (p. 298), was referred to. Several experiments were performed to show that the cell is a thermo-electric one. "It was shown (we quote the Society's *Journal*) that, at low temperatures, while the caustic alkali contained considerable water, the carbon was positive to the iron; but that at a high temperature, after the alkali had become highly dehydrated, the carbon was negative to the iron. The carbon rod was replaced, successively, by rods of brass, copper, German-silver, and iron, without appreciably affecting the result, and a current of illuminating gas was passed into the fused alkali in place of the current of air employed by Jacques. The result was unchanged, showing that the action of the current of air was not to produce oxidation, but to cool the upper layer of the alkali."

IF the stability of a nation is measured by the amount of care bestowed upon forests, the power of Germany is not likely to decline. Mr. G. A. Daubeny contributes to *Nature Notes* a chatty account of forestry in Germany, where more than twenty-five per cent. of the land is covered with trees. In Prussia, twenty-three per cent. is forest; but in England the proportion of forest land is small—only four per cent. There is quite an army of foresters in Germany—about twelve thousand in all—and, as is well known, these officials receive a thorough training in all the branches of their subject. Mr. Daubeny ascribes the decayed power of Syria, of Greece, and of Spain to the neglect of their forests, and urges the afforestation of land as a means of developing national resources. "Den Wald zu pflegen, bringt allen Segen," says a German proverb; and even if the care of forests does not bring every good, it adds considerably to the wealth of a nation.

UNDER the title "Publications of the Smithsonian Institution," by Mr. W. J. Rhees, a list of a number of papers printed from the Institution's Contributions to Knowledge, Miscellaneous Collections, and Annual Reports, for sale or exchange, has been issued. The papers are classified according to a comprehensive scheme of subjects, and are fully indexed. Every student of science will find in the list works which he will be anxious to possess.

WE have received from Messrs. Marcus Ward and Co. a small portfolio of forty coloured prints of common native and introduced plants found in Manitoba. There is no explanatory letter-press, and nothing to show whether there are more to come or not. All we can say for them is that the figures are tolerably well drawn, though often crudely coloured. Still they are recognisable, and may prove serviceable to persons who wish to know the names of plants growing in their neighbourhood.

LOCAL scientific societies keep alive the spirit of inquiry, but they often err on the side of dilettantism. We are afraid the *Proceedings* of the Bath Natural History and Antiquarian Field Club comes into this category, for though the number (vol. viii. No. 3) just received contains a helpful paper by Mr. A. Smith Woodward on the collection of fossil fishes from the Upper Lias of Ilminster, in the Bath Museum, and some notes of local antiquarian interest, there is also a description of an excursion to witness a diviner's experiments in water-finding. It would be well if societies like that at Bath would help more seriously to extend natural knowledge than many of them do at present.

TWO ponderous volumes of the "Palæontologia Indica"—a publication which, as every geologist knows, is devoted to the description and illustration of organic remains procured during the progress of the geological survey of India—have lately reached us. In one of them (Series xiii. vol. ii. part i.), Dr. William Waagen continues his work on "Salt-Range Fossils" by descriptions of the fossil contents of the Ceratite beds. These beds are believed to represent the Trias of Europe, but it is not possible to say exactly what parts of the Trias are represented by them, though Dr. Waagen's contribution will enable the question to be profitably discussed. The fossils which are obtained from the Ceratite formation of the Salt-Range are chiefly Cephalopoda, only a few remains of fishes having been found. The present volume contains the determinations of the genera of the few specimens available, but by far the greater part of it is devoted to the Ammonoids. The specific descriptions of the fossils, and the remarkably fine plates which illustrate them, will prove of prime importance in the further consideration of the classification of that order. In the definition of the genera and families treated by Dr. Waagen, the groups are minutely characterised, but the developmental connection is only kept in sight so far as it has been demonstrated. It is held that, in the present state of our knowledge, it is undesirable to do more than arrange the single genera according to their affinities in smaller groups, or families. Dr. Waagen's memoir will, however, enable the developmental relations to be more fully worked out than has previously been possible.

THE second memoir referred to in the foregoing note belongs to Series xv. of the "Palæontologia Indica." In it Dr. Carl Diener describes "The Cephalopoda of the Muschelkalk." The volume is a monograph on the Cephalopoda of the Muschelkalk—a distinct geological horizon in the Himalayan Trias, regarded by Dr. E. von Mojsisovics as a connecting-link between the triassic Mediterranean and Arctic-Pacific provinces. Dr. Diener has used a wealth of palæontological materials in preparing his work, and his interpretation of them is a valuable contribution to the knowledge of the triassic fauna of the Himalayas. In a third publication to which we must call attention (*Memoirs* of the Geological Survey of India, vol. xxvii. part 1), Dr. F. Noetling describes "Some Marine Fossils from the Miocene of Upper Burma." Sixty-nine species are described, and fifty-one have been determined. From these identifications it is seen that the fauna represents a marked Indian facies, slightly sprinkled with a more Southern element from Java.

AT the beginning of last year it was decided by the United States Congress that future annual reports of the Department of Agriculture should be divided into two volumes: first, an executive and business report; and second, a volume "specially suited to interest and instruct the farmers of the country," made up of papers from the Department bureaus and divisions. This latter volume ("Yearbook of the Department of Agriculture, 1895") has recently been distributed, and it will undoubtedly extend agricultural knowledge in the United States. In the first place, the volume contains a general report of the operations of the Department during 1895. Then there is a series of thirty-three essays by experts, discussing in easy language the results of investigations in agricultural science and new developments in farm practice. As years go on, successive issues of Yearbooks of this kind will give farmers a good library covering the applications of science to practical agriculture. In an appendix, a large amount of miscellaneous information, taken from the reports of the Department, is presented with especial regard to the agricultural reader. It is impossible for us even to enumerate the many papers contained in the volume. Valuable data, facts of interest, recipes, directions with regard to agricultural practice, and descriptions of the relation of forests to farms, insect pests, principles of pruning, soil ferments, common birds of the farm and garden, and co-operative

road construction are given in an instructive and interesting form. To quote the words of Mr. C. W. Dabney, Assistant Secretary of the Department: "It has been sought to make the volume a concise reference book of useful agricultural information based in great part upon the work of this and other Departments of the Government, without making it an encyclopædia of general information. In brief, the effort has been to make a book, and not a mere Government report—a book worthy to be published in an edition of half a million copies and at an expense to the people, if we count both publication and distribution, of over four hundred thousand dollars." The money thus spent in disseminating accurate knowledge of agricultural investigations may appear excessive, but it will be returned to the country a hundred-fold.

THE additions to the Zoological Society's Gardens during the past week include a Black-faced Kangaroo (*Macropus melanopus*, ♂) from Australia, presented by Mr. G. T. Wills; a Loder's Gazelle (*Gazella loderi*, ♀) from Oued Souf, Algeria, presented by Mr. A. B. Birdwood; a Gazelle (*Gazella* ——), two Hairy-footed Jerboas (*Dipus hirtipes*), a Spot-bellied Snake (*Zamenis ventrimaculatus*), an Ocellated Sand Skink (*Seps ocellatus*) from Arabia, presented by Dixon Bey; a Common Cormorant (*Phalacrocorax carbo*), British, presented by Miss G. Howell; two Passerine Parrots (*Psittacula passerina*) from South America, presented by Miss L. Scott Moncrieff; a Brown Capuchin (*Cebus fatuellus*) from Guiana, a Grey Ichneumon (*Herpestes griseus*) from India, deposited; two Patagonian Cavies (*Dolichotis patachonica*), two Ypecaha Rails (*Aramides ypecaha*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

BROOKS'S COMET.—This comet, which M. Javelle, of Nice, has fortunately re-discovered, remains so faint an object, that other observations for the improvement of the elements, computed by Dr. Bauschinger, are still wanting. The one position secured has been utilised to correct the mean motion, and consequently the time of perihelion passage. This will take place November 4·18375, Berlin mean time, or only 0·2083 days later than the time determined from the last appearance. The excentricity needs probably a small correction, but the data for its determination are not yet existing. The following ephemeris, for Berlin midnight, is derived from the corrected mean motion and time of perihelion passage.

1896.		R.A. h. m. s.	Decl. ° ′ ″	Brightness.
Aug.	13	22 32 43·50	−18 54 24·1	1·8
	16	30 58 66	18 59 1·0	1·9
	20	28 26·73	19 4 4·9	1·9
	24	25 44·87	19 7 30·7	2·0
	28	22 58·22	19 8 52·5	2·0
Sept.	1	20 11·78	19 7 49·1	2·1
	5	17 31·14	19 4 1·2	2·1
	9	15 2·04	18 57 10·7	2·1
	13	12 49·63	18 47 8·8	2·0
	17	10 58·23	18 33 53·0	2·0
	21	9 31·79	18 17 22·7	2·0
	25	8 32 66	17 57 45·6	2·0
	29	8 2·93	17 35 8·0	1·9

For finding the comet, the bright star Fomalhaut will still be convenient, the region comprised in the ephemeris being about 11° north of the star, and on the meridian (London) about 1·45 a.m.

METEOR TRAILS.—We noted on July 30 (p. 301) that attention has been called by Prof. Johnstone Stoney and others to the desirability of observing the meteors in November next, which are likely to form part of the great November shower, particularly with the view of settling the question of the date at which the shower was introduced into the solar system. Improved methods of observation might have been expected to furnish more accurate information, and lead to a closer approximation to the orbit. It is therefore disappointing to read in the Report issued by Dr Elkin, the Director of the Yale Observatory, that, notwithstanding repeated efforts, no photographic records of meteor trails have been secured. The apparatus was in use for the August meteors, but none were of sufficient brilliancy to impress themselves upon the film, which had become somewhat fagged by the strong moonlight. Other occasions were equally disappointing; but the Director is not discouraged, and in place of the two lenses now employed he hopes to substitute the complete battery of lenses for which the mounting was originally planned.

PERSONAL EQUATION IN OBSERVING TRANSITS.—The vexed question of the existence and necessary removal of personal equation in determining clock error has been attacked by Mr. R. H. Tucker, of the Lick Observatory. The particular form of the question to which Mr. Tucker has applied himself is that raised some years since by Prof. van der Bakhuyzen, of the effect of the brilliancy of the star on the time of transit determined by chronographic registration. Mr. Tucker placed over the object-glass four thicknesses of wire netting, which reduced the magnitude of the star 4·1 magnitudes, or, in other words, destroyed all but one forty-fifth part of the original light. The clock error was determined from the observations of stars, with and without the screen alternately, with the result that the faint stars were observed 0·037s. later than when seen at their full brilliancy. The correction to observed right ascension is −0·009s. for each magnitude, with a probable error of ±0·001s.

RECENT RESEARCHES ON RÖNTGEN RAYS.

THE subjoined summary brings together in a convenient form for reference a number of researches on Röntgen rays which have recently come under our notice. It will be seen that a large amount of detailed information with reference to the character and capabilities of the rays is being accumulated by investigators in various parts of the world.

Dr. A. Dupré, F.R.S., writes, under date July 29:

"The article by Mr. Benjamin Davies, in your issue of July 23, has recalled to my mind certain experiments of my own, made several months since, which may perhaps throw some light on Mr. Davies' results. I was then working with various vacuum tubes, and among others with an ordinary Geissler tube containing nitrogen, such as is used for obtaining spectra of gases. The capillary part of this tube gave a brilliant light, which had the power of inducing fluorescence of many substances, to a remarkable degree, the light falling direct on to the substance. The tube being in action, the screen covered with platino-cyanide of potassium fluoresced strongly ten feet from the tube, the active surface being towards the tube. This was, of course, to be expected, but, to my astonishment, the fluorescence was almost equally noticeable when the back of the screen was turned towards the tube, and remained so even when I interposed a book, a board, a sheet of tin-plate, or the human body between the tube and the screen. When, however, I placed my hand against the back of the screen, no trace of a shadow was noticeable; the same was the case when pieces of metal, or other objects opaque to the Röntgen rays were so placed. The screen all the while remaining strongly and uniformly fluorescent. This seemed to me to show that, whatever the nature of the rays producing the fluorescence of the screen, they could not be Röntgen rays; and I concluded that the fluorescence was really due to light striking the front, or active, surface of the screen after reflection, either from the walls of the room, or, perhaps, from the air. When accordingly all possibility of any light thus reaching the screen was excluded, all fluorescence was effectually stopped. Might it not be possible that in Mr. Davies' experiment the fluorescence of his screen was in part, at least, induced by rays reaching the active surface of the screen after reflection? Thus accounting for the fact that the hand cast no shadow whatever."

Mr. J. A. M'Clelland read a paper on the "Selective Absorption of Röntgen Rays" before the Royal Society on June 18. The experiments described in the paper were made to determine whether or not the Röntgen rays given off by a vacuum bulb were of a homogeneous nature, by examining the manner in which they are absorbed by different substances. The substance whose absorptive power was to be examined—say, a plate of glass—was placed so that the rays traversed it before falling on a charged disc, which was in connection with a pair of

quadrants of an electrometer. The disc was discharged by the rays, and the transparency of the substance was measured by the rate at which the spot of light from the electrometer needle moved across the scale. Sheets of tinfoil were then substituted for the glass, and the number—n, say—taken, such that the rate of discharge of the disc was approximately the same as with the glass. The rate of discharge was accurately measured in the two cases. The ratio of the rate of discharge with the glass to that with the n sheets of tinfoil gave a measure of their relative transparency to Röntgen rays. The rays were then made to pass through a number of sheets of tinfoil, and then through the glass, and the rate of discharge measured. The glass was removed, and the same n sheets of tinfoil as were formerly used put in its place, and the discharge again measured. The ratio of the rate of discharge in the latter two cases was a measure of the relative transparency of the glass and the tinfoil sheets to Röntgen rays which had been already screened by passing through tinfoil. If the Röntgen rays were all of one kind, the two ratios thus obtained should be equal, but a difference in the ratios could only be explained by assuming that the rays were not homogeneous, and that some were more readily absorbed by the tinfoil, and others by the glass or other substance used. Various substances were tested against tinfoil in this manner. With some there was no selective absorption, with others it was very marked. Glass gave none, with mica and paraffin the effect was small, with fuchsine, eosine, and a number of other substances the effect was very marked. A table, given in the paper, showed the results obtained with these and other substances. The author concluded that the Röntgen rays are of different kinds, and that the substances given in the table differ very much from tinfoil in their selective absorption. It is important to observe that these results were obtained with a vacuum bulb which was working extremely well and discharging the disc very rapidly. With another bulb, which was not nearly so efficient, no evidence of selective absorption could be obtained. The radiation from this bulb was homogeneous as far as could be determined by this experiment. With a third bulb, better than the last, but not so good as the first, selective absorption was obtained, although less marked than with the first bulb. It seems, therefore, that as a tube becomes more efficient the character of its radiation becomes less homogeneous.

The effect of Röntgen rays in discharging electrified bodies continues to form the subject of investigation of several Italian physicists, whose conclusions may with interest be compared with the results obtained by Prof. J. J. Thomson in this country. Prof. Emilio Villari (*Atti della R. Accademia dei Lincei*) enunciates the following conclusions, in support of which an elaborate series of experiments are fully described. (1) The discharge of a conductor in air, when provoked by Röntgen rays, takes place by an electrical convection of the particles of air set in action by the radiations. (2) The discharge is retarded if the surface of the electrified conductor exposed to the air is diminished by covering part of it with paraffin. (3) When the conductor is covered all over with paraffin placed in contact with it, the discharge stops almost immediately after it has been started by the Röntgen rays. A little electricity conveyed by the surrounding film of air charges the paraffin, and further discharge was prevented. (4) If the conductor is surrounded by air enclosed within a tube of paraffin, and subjected to Röntgen rays, the discharge at first takes place fairly rapidly, but subsequently proceeds extremely slowly. The electricity carried off as usual by the air suddenly charges the walls of the tube, and afterwards is dispersed with difficulty. (5) The electricity dispersed by the body can be collected on a tube of paraffin, as in the preceding case, or on an insulated metal tube surrounding the discharged body. This collected electricity can be observed with an electroscope, and it is, of course, of the same kind as that of the body. (6) Metal tubes, whether insulated or not, surrounding the electroscope, serve to condense on it the charges imparted to them. They retard the discharge produced by Röntgen rays, either on account of the quantity of electricity accumulated by them, or owing to their imperfect transparency to the rays.

Prof. Augusto Righi (*Atti della R. Accad. dei Lincei*) also *still* considers it "non proven" that any but a gaseous dielectric becomes a conductor under the influence of Röntgen rays, thus agreeing substantially with Prof. Villari. Prof. Righi, however, has discovered a source of error in his previous experiments, which, however, does not affect this result. If in front of the aluminium window of a leaden box containing the Crookes' tube, a large disc of lead is placed, and the charged body is situated in the geometrical shadow cast by the disc, it might be supposed that no discharge would take place; but such is far from being the case, except when the leaden disc is closely pressed against the window.

In the succeeding number of the *Atti dei Lincei* this deflection of Röntgen rays behind opaque bodies is discussed at considerable length by Prof. E. Villari, who claims to have recorded the phenomenon as long ago as March last. Observations were made on the discharge of an electroscope placed in different portions of the shadow cast by a plate of lead, and, moreover, photographic impressions were obtained upon a sensitive plate placed just inside the geometrical umbra. Signor Villari concludes, that in order to discharge an electroscope it is not necessary that Röntgen rays should fall directly upon it. The presence of air previously traversed by these rays is sufficient to promote the discharge—a result in accordance with one o Prof. Röntgen's original observations.

In a subsequent paper in the same publication, Prof. Righ proves that the discharge of electricity produced in air by Röntgen rays takes place by convection *along the lines of electrostatic force*. The experiments were made by means of an insulated conducting sphere placed in the presence of a disc of ebonite having its lower side covered by a metal armature. Between the two a cross of ebonite was placed, and the conductor and armature were oppositely charged. After exposing the whole to the action of Röntgen rays for a few minutes, the ebonite was dusted over with a mixture of powdered red-lead and sulphur, when the shadow of the cross appeared red on a yellow background. In another experiment a cylindrical conductor was substituted, and the shadow was produced by a strip of ebonite placed parallel with its axis. The observed position of the shadow agreed exactly with that calculated from the form of the lines of electrostatic force, which in this case were, of course, coaxial circles.

It should be observed, however, that if the phenomenon were one of *conduction* instead of convection, the discharge would still follow the lines of force, just as in Prof. Righi's experiments.

The same indefatigable observer (Prof. Righi) also discusses in the *Comptes rendus* a paper by MM. Benoist and Hurmuzescu, who find that, "if Röntgen rays can develop an electric charge . . . this effect does not exceed the order of magnitude of the electromotive forces of contact." Prof. Righi finds that the positive potential to which an insulated conductor is raised when Röntgen rays fall on it, *is precisely* of that order of magnitude. In the experiments of MM. Benoist and Hurmuzescu, the electrometer and the conductor experimented on were enclosed in an uninsulated metal case; in Prof. Righi's experiments the case was made to enclose the Crookes' tube, which was placed at a considerable distance from the conductor, so as to remove the latter as much as possible from the influence of all conducting bodies. It appears probable that both dispositions are equally good.

Under the title "Raggi Catodici e Raggi-X" (*Nuovo Cimento*), Prof. Battelli and Dr. Garbasso give a continuation of their researches bearing chiefly on the question of whether there is really an essential difference between Röntgen rays and kathodic rays. These writers are of opinion that the two kinds of radiations do not differ from one another in any more essential characteristics than those which enable us, for example, to distinguish two flames of different colour.

In a further contribution to the *Nuovo Cimento*, Prof. Battelli and Dr. Garbasso examine the resemblance between Röntgen rays and ultra-violet light in their power of dispersing electric charges. The experiments, which were made by employing alternately a Crookes' tube and a voltaic arc with the same disposition of apparatus, lead to the conclusion that although ultra-violet light acts on electrified bodies in the same manner as Röntgen rays, the modification produced in the surrounding air (in the case of ultra-violet light) is less pronounced and less stable.

An important point in connection with the debated nature of Röntgen rays is the determination of their wave-length, which has been successfully effected by Dr. L. Fomm, of Munich (*Sitzb. der Bayerischen Akademie*, xxvi. ii.). As these rays show no measurable reflection or refraction, the only way available was by diffraction. The Röntgen rays emanating from a large Hittorf tube were made to pass through a brass slit 0·5 mm. in breadth, and, after being diffracted by a second slit, were received on the photographic plate. The

width of the second slit could be varied from 0·1 mm. up to 2 mm., and with the former width an exposure of fifty minutes was required. As long ago as March last, Dr. Fomm obtained photographs showing interference bands, thus affording proof of the undulatory nature of Röntgen rays. By starting with a very narrow slit and gradually increasing its width, the interference lines approach closer together, until a dark line—the first minimum—appears in the centre. As the opening becomes still wider, this minimum gives place to a maximum with two minima, one at each side, and so on, and by means of Lommel's formula, the wave-length can be determined from this phenomenon. Dr. Fomm obtains $\lambda = 0.000014$ mm., so that the wave-length is about fifteen times smaller than the smallest wave-length hitherto observed in the ultra-violet. Owing to the difficulty of determination, Dr. Fomm regards this number as giving the upper limit rather than the exact measure of the wave-length of the observed rays. Meanwhile MM. G. Sagnac, L. Calmette, and G. T. Lhuillier have published investigations in the same direction (*Comptes rendus*, cxxii. 13 and 16). M. Sagnac uses a wire grating, and from a scarcely measurable diffusion of the image of the slit he obtains 0·00004 as an upper limit to the wave-length. MM. Calmette and Lhuillier have made diffraction experiments with two slits, and have obtained bright and dark lines without expressing an opinion as to the wave-length of the rays.

Another closely allied question is whether Röntgen rays consist, like ordinary light, of radiations whose wave-lengths vary over a considerable range. Such differences of wave-length give rise in the case of light to the phenomenon of colour, and the corresponding phenomenon for Röntgen rays has been studied by Dr. F.-V. Dwelshauvers-Dery (*Bulletin de l'Académie Royale de Belgique*, No 6) under the name of *actinochroism*. Observing that differences in the degree of exhaustion of a Crookes' tube might be expected to give rise to differences of wave-length in the emitted rays, and that the higher the vacuum the shorter would the wave-lengths probably be, Dr. Dwelshauvers-Dery has examined whether certain substances are more transparent for certain Röntgen rays than for others. For this purpose, their transparencies were compared by placing the substances in front of a fluorescent screen and observing their shadows side by side with that of a test-object consisting of laminæ of tinfoil, whose total thickness could be varied at pleasure. To obtain the necessary variation in the nature of the Röntgen rays, it was found sufficient to compare the radiations from a new tube, which had not been previously used, with those emanating after the tube had been in action for some time. The observations were repeated on the new tube after a quarter of an hour, half an hour, an hour, an hour and a half, and two hours respectively, and transparency-curves obtained by plotting the results on paper. These curves show that (1) the transparency of every specimen, with the exception of obsidian, increases during the first few minutes; (2) agate and alum, after increasing in transparency for some time, become more and more opaque; (3) obsidian continually diminishes in transparency. It is, of course, here a question of relative transparency with respect to tin. Although we have no measure of the variations of the absolute transparency of the tin itself, the experiments suffice to prove that the absolute transparencies of different substances vary according to the state of the tube, and it is therefore, not considered hazardous to explain these variations by the actinochroism of Röntgen rays.

The same phenomenon has been observed by MM. Benoist and Hurmuzescu and, perhaps, by other physicists. In some of Mr. A. A. C. Swinton's experiments it will be remembered that the properties of Röntgen rays, and particularly their power of penetrating through organic tissues, varied with the degree of exhaustion of the vacuum.

Two papers on Röntgen rays appear in a recent *Bulletin de l'Académie Royale de Belgique* (No. 5). One, on the probable cause of the production of Röntgen rays and of atmospheric electricity, and on the nature of electricity, is by P. de Heen. Judging from the analogy of a pith ball oscillating between two electrified plates, and from the comparative sizes of the pith ball and the air molecule, it may be assumed that the molecules have a velocity of 330,000 metres per second. This agrees fairly well with J. J. Thomson's estimate of a velocity of 200,000 m. per second for the kathodic projections. Such a velocity corresponds to the excessively high temperature of 46 million degrees. Hence, wherever these molecules impinge upon a surface, they will produce ether waves of very high frequency. These waves are probably identical with Röntgen rays, which are therefore very short ultra-violet waves. The author also claims to have proved that an electrified surface impresses a sensitive plate quite apart from any radiating action. He proposes the theory that positive and negative electricity are propagated in different ways, the former by transverse, the latter by longitudinal, waves. Atmospheric electricity is generated by masses of gas emerging from the interior of the sun (protuberances), which send out ultra-violet waves, and charge the atmosphere positively and the earth negatively by induction.

The reflection of Röntgen rays is treated by F. V. Dwelshauvers-Dery, in the *Bulletin* referred to in the foregoing paragraph. No trace of a regular or geometric reflection of Röntgen rays can be discovered. The wave-length of the rays is evidently too small in comparison with the size of the molecules. In order to find whether there was any diffuse reflection, the author placed a sensitive plate with the film downwards. A piece of ruby paper half covered the film, and sheets of zinc, brass, copper, tin, and collodion were placed under this. Then followed a second plate with the film upwards. On exposing the whole to Röntgen rays, both transmission and reflection could be studied. As regards the former, it was found that collodion increased the activity of the rays. This fact may be utilised to diminish the exposure, a sheet of collodion being placed above the object and the film. Impressions were also obtained on the upper plate, apparently due to diffused reflection. The order of reflective power was: tin, zinc, copper, brass, iron, platinum, gold, lead, aluminium. Hence tin placed below the film may also be used to diminish exposure. The state of polish of the surface was without influence, which shows that there was no regular reflection. But the most important fact is that the ruby paper intercepted a large proportion of the reflected rays. Hence the latter are not Röntgen rays proper, but rays of greater wave-length, and it may be maintained that X-rays are not reflected as such.

Herr W. Arnold (*Centralblatt für Nahrungs- und Genussmittel-Chemie sowie Hygiene*) shows that Röntgen rays can be employed with considerable success in the detection of food adulteration. Carbohydrates, fats, and aniline dyes were found to be very transparent to these rays, though slight differences were noticeable. Among the vegetable oils the order of transparency was: (1) castor oil, (2) almond oil, (3) olive oil of Provence, (4) poppy oil, (5) oil of sesame, (6) linseed oil; the difference between the last five was very slight, but castor oil was considerably more transparent. Of fats, butter was the least transparent, lard came next, and margarine was the most transparent; while the opacity of a mixture of different fats was found to vary with the percentages of its constituents. Among the spices, Herr Arnold found that the transparency decreased as the proportion of ash increased, so that saffron was the least and pepper the most absorbent of Röntgen rays. Foreign matter mixed with spices, such as brick-dust, ochre, sand, &c., was conspicuous, while adulterations of flour with powdered fluor or other spar, or chalk, could readily be detected. Earthenware glazes containing lead differed strongly from ordinary glazes, since, of all substances, lead offers the greatest resistance to the passage of Röntgen rays. For colouring matters imbedded in gelatine the order was: (1) methylene blue, (2) cyanin, (3) methyl violet, (4) eosin, (5) fuchsin, (6) brown, (7) orange, (8) chrysanilin, (9) fluoresin; the order must thus be blue, red, yellow, so that the lightest colours are the least transparent. In wines the transparency decreased as the proportion of sugar increased, just as generally the absorbing power of fluids increased with their specific gravity, and that of the elements with their atomic weight. In salts, the radical had considerable influence, and arseniates, sulphates, and phosphates exhibited a far greater power of absorbing the rays than chlorides.

The same writer also discusses the luminosity of solids under the influence of Röntgen rays. Referring to the use of fluor spar in shortening the time of exposure of radiographs, as employed by Winkelmann and others, Herr Arnold states in the *Apotheker-Zeitung* that he and Herr Forster-Bern have obtained negative results, as no difference was noticed between the action of the rays on plates exposed with and without the spar; possibly this was due to the quality of the spar employed. In the *Zeitschrift für Electro-chemie* he states the results of a long series of observations on various forms of luminosity, namely, thermo-luminosity, kathodo-luminosity, and what he proposes to call "X-luminosity." Herr Arnold finds tungstate of lime to

be the most luminous of all salts under the action of Rontgen rays, especially when in the form of the mineral known as tungsten. He thinks it exhibits the phenomena even in a more marked degree than platino-cyanide of barium. A solution of tungstate of copper in tungstate of calcium, moreover, glows with the same brightness as natural tungsten. A note on the best form of tungstate of calcium for showing fluorescence has also been published by Dr. Ferdinando Giazzi, of Perugia. By a certain process of heating in a coke furnace in the presence of oxygen, the tungstate is reduced to a white saccharoid mass which gives a much more brilliant glow than ordinary tungstate, but the effect can be further intensified by pulverising the mass and repeating the process, the final product which Dr. Giazzi calls the "bisaccharoid" form being, in his opinion, the best substance for shortening the exposure and intensifying the brilliancy of photographs taken with Röntgen rays.

Prof. Giuseppe Martinotti (*Rivista Scientifico-Industriale*) claims to have obtained shadow photographs of metal objects by the use of different kinds of light (including that of bisulphide of carbon), the light from a sulphur flame being found the best. Perhaps the radiations by which these results were obtained may be identical with Le Bon's *lumière noire*. This latter phenomenon deserves to be more fully investigated by physicists than has been done.

At a recent meeting of the *Société Française de Physique*, a discussion took place on a new arrangement of vacuum tube introduced by M. Colardeau, which gives, with short exposures, great clearness of images. The ordinary "focus" tubes are, according to M. Colardeau, open to several objections; amongst others, the thickness of the glass required to stand the external pressure arrests the passage of a large proportion of the rays; the energy of the discharge is not sufficiently concentrated round the kathode, and the distance between the kathode and anti-kathode is too great. The new form of tube is a cylinder of not more than 6 or 7 mm. diameter, containing a concave kathode of 4–5 mm. radius of curvature, which nearly fills the width of the tube. The lamina inclined at 45°, forming the anti-kathode, is only 7–8 mm. distant from the kathode, and just opposite the focus; and the glass of the tube is blown out into a hemispherical knob 1/10 mm. in thickness; the latter offers but little resistance to the passage of the rays generated at the focus. With this disposition stereoscopic radiographs were taken, which stand out in remarkable relief. The tube has stood the test of a discharge from a coil of very large dimensions without the least injury.

Finally, we would call attention to the excellent radiograph of an entire newly-born child taken by Prof. A. Imbert and M. H. Bertin-Sans, of the University of Montpellier, which is reproduced in the *Revue Générale des Sciences* for June 30. In sharpness of outline and general detail it far excels anything previously attempted in this direction.

METALLIC CARBIDES.

UNTIL about three years ago, the only definite compounds of carbon with metals whose existence had been proved with certainty were the acetylides of some of the metals of the alkalis and alkaline earths, and these were only known in an amorphous and impure state. The construction of the electric furnace by M. Moissan in 1893, in which the heating power of the electric arc was directly utilised, by extending the upper limit of working temperatures, added a powerful instrument of research to the laboratory. Among the many new fields of work thus opened up, the preparation of the difficultly reducible metals, such as tungsten, molybdenum, manganese and chromium, was attacked with much success by M. Moissan. These reductions being necessarily effected in the presence of carbon, the formation of definite metallic carbides of great stability soon became apparent, the properties of which proved to be of such interest that their preparation was systematically attempted. Certain metals, such as gold, bismuth, lead, and tin, do not form carbides at the temperature of the electric furnace, neither do they dissolve any carbon. The metals of the platinum group dissolve carbon with facility, but deposit the whole of it on cooling in the form of graphite, the metals being unchanged. Copper, silver and iron take up carbon in quantities that, although small, are sufficient to cause marked changes in the physical properties of the metals; it is noteworthy that no definite crystalline compound could be obtained with iron. On the other hand, fused aluminium takes up carbon readily with formation of the crystalline carbide Al_4C_3, and the oxides of many other metals furnish similar crystalline compounds when heated in the electric furnace with an excess of carbon. The behaviour of these substances with water furnishes the most convenient mode of classification. The carbides of molybdenum, Mo_2C, of tungsten, W_2C, of titanium, TiC, of zirconium, ZrC and ZrC_2, and of chromium, Cr_4C and Cr_3C_2, do not decompose water at the ordinary temperature. Of those reacting with water, the carbides of lithium, Li_2C_2, calcium, CaC_2, strontium, SrC_2, and barium, BaC_2, furnish pure acetylene; of aluminium, Al_4C_3, and of beryllium, Be_2C, pure methane; of manganese, Mn_3C, a mixture of equal volumes of hydrogen and methane; whilst the metals of the cerite group give crystalline carbides of the type RC_2 (CeC_2, LaC_2, YC_2, and ThC_2), all of which react with cold water, forming a complicated gas mixture containing hydrogen, acetylene, ethylene, and methane. But the most complex reaction is that furnished by uranium carbide, U_2C_3, with water. In this case, in addition to a gaseous mixture containing methane, ethylene, and hydrogen, liquid and solid hydrocarbons are produced in abundance, more than 100 grams of liquid hydrocarbons being obtained in one experiment from four kilograms of carbide. Cerium and lanthanum carbides have also furnished small quantities of solid and liquid hydrocarbons.

With the exception of chromium and zirconium, which form Cr_4C, and Cr_3C_2, ZrC_2, and ZrC respectively, only one carbide of each metal appears to exist, the formula of which is usually simple, and not always in accordance with what would be expected from the position of the metal in the periodic system. Thus, whilst the carbides of calcium, strontium, and barium have the formulæ CaC_2, SrC_2, and BaC_2, and yield pure acetylene upon treatment with water, beryllium forms Be_2C, from which pure methane is obtainable (Lebeau). As already mentioned, aluminium forms Al_4C_3 giving pure methane, whilst the higher members of the same group, yttrium and lanthanum, give YC_2 and LaC_2, yield, with water, complicated mixtures of acetylene, hydrogen, ethylene and methane, together with some liquid hydrocarbons. Cerium and zirconium, again, which are closely allied in the periodic system, form carbides having totally different properties, CeC_2 giving acetylene and methane with water, ZrC and ZrC_2 being unattacked under the same conditions.

These discoveries have already been applied technically in two directions—in the commercial production of acetylene from calcium carbide for enriching coal gas or for burning alone, and in the production of the carbides of silicon, CSi (discovered by Acheson), and of titanium CTi, both of which are extremely hard, the latter even cutting diamond. In organic chemistry, also, they afford a direct synthesis of many hydrocarbons, and offer a means of preparing pure methane and acetylene in large quantities. But perhaps their greatest interest lies in their bearing on certain geological problems. Starting with the fact that cast iron on solution in dilute acids gives a mixture of hydrocarbons, Bjasson and Mendelejeff twenty years ago suggested, independently, that the deposits of petroleum may be due to the infiltration of water into molten masses of metallic carbides, and this view was supported by an observation made about the same time by Silvestri, that some lavas of Etna contained petroleum.

In discussing this question in the light of his own observations, described before the Royal Society on June 18, M. Moissan protests against too hasty generalisation in this matter, as petroleums of different origins may exist, there being clear evidence in some cases that bituminous schists have been formed by the decomposition of organic matters. On the other hand, there is the continuous evolution of methane at Bulgonak and in Pennsylvania, which might well be formed by the action of water upon aluminium carbide; the presence of free hydrogen in the submerged volcanic vents at Santorin (Fouqué), and the occurrence of petroleum and carbonaceous products towards the end of a volcanic eruption, the violence of which would be fully accounted for by the supposition of the entry of water upon metallic carbides at a high temperature. There is also the possibility of explaining the occurrence of petroleums of different composition, for whereas a deposit of the carbides of the alkaline earths would yield acetylene, which at the extremely high temperature necessarily produced and in presence of free hydrogen might be expected to yield hydrocarbons of the Russian type, the carbides of aluminium and uranium, at perhaps a lower temperature, might account for petroleums of the American type. The whole work is extremely suggestive to vulcanologists, and will doubtless result in further investigation on the geological side.

G. N. H.

ITALIAN SCIENTIFIC EXPEDITION TO MONTE ROSA.

Referring to the letter published in Nature (No. 1307, November 19, 1894), we have been able this year to complete our researches on the waters of the Monte Rosa from the highest summit down to the glacial streams and lakes at about 2000 metres above the sea level.[1] Having carried up to our laboratory on the Lavez Alp (2450 m.) a good analytical balance, some quantitative determinations could be made on the spot. As might be anticipated, the amount of suspended matter in the water of the streams issuing immediately from the glaciers varies considerably not only on different days, but even in the same day. While on a cold, snowy day (August 3), the water of the Indren torrent contained 0·011 gr. (per litre) of sandy detritus, sixty times as much (0·66 gr.) was found on August 10, on an exceedingly warm, sunny day. On a regular summer day, with a mean temperature, the amount of suspended matter in the Indren waters varies from 0·010 gr. in the early morning to 0·09 gr. in the afternoon.

This matter is composed of two kinds of sand: one coarser, which sinks to the bottom in a few hours, and can be severed at once by filtering; and a subtler one, which remains permanently suspended in the waters, passes through the paper, and may only be determined by allowing the water to evaporate and extracting the residue with distilled water to dissolve the soluble salts. The ratio of the two kinds of suspended sand varies with the temperature; the finer one being very scarce, about 14·3 per cent. of the total amount on an average day, rising to 42·0 per cent. when the heat is very great, and when the melting of the ice proceeds with great intensity and speed. This seems to indicate a different origin of the two constituents; the coarse sand being perhaps spread over the surface of the ice fields, and the fine one being enclosed within the glacial masses.

In winter the melting of the glaciers is considerably reduced, and the waters of the Lys, which drain the valley of Gressoney, are nearly clear and transparent.

The amount of dissolved matter—the so-called fixed residue—in the different waters is shown in the following table.

	Milligr. per litre.
Loose, granular ice of the Punta Gnifetti (Signal Kuppe 4561 m.)	16·9
Compact ice of a crevasse at the foot of the Vincent Pyramid (3700 m.)	2·4
Compact ice near the Capanna Gnifetti (ab. 3600 m.)	13·9
,, ,, ,, ,, ,,	8·8
Surface ice of the Garstelet glacier (3300 m.)	1·6
Water of the Salzia lake (2670 m.)	27·2
Water of the Gabiet lake (2339 m.)	25·1
,, ,, ,, ,, ,, ...	23·1
,, ,, Sella spring (about 2250 m.)	30·8
,, ,, Indren torrent (about 2400 m.)	16·1
,, ,, ,, ,, (on a hot day)	21·2

The water obtained from the melting of the ice of the glaciers is the purest of all, in some instances nearly as pure as distilled water. It is very interesting to remark that the amount of dissolved salts in the samples taken in the same glacier, and even in the same spot, is never constant; this shows that the different snow and ice streams which descend from the buttresses of the mountain to form one great ice river, while compressed side by side with the others, still retain their own individuality, and are not confounded together in a uniform mass.

The residues of the waters consisted of sodium and calcium, together with sulphuric and hydrochloric acid; sulphate of lime was prevalent in the lakes and in the Sella spring, the latter showed also the presence of carbonates. Iron (dissolved) was found in traces here and there in the ice-waters. The suspended matter (sand) consisted of silicates with a large amount of iron.

As stated in my letter already referred to, the ice of Monte Rosa contains small quantities of ammonia; the maximum, of 0·3 milligr. per litre, was found in a block of ice at the foot of the great Glacier du Lys, about 2150 m. The waters of streams, lakes, and springs show no ammonia; only during a very hot day the waters of the Indren, which were turbid with an unusual amount of sand, contained a little ammonia, which disappeared in a few hours; the oxygenated compounds of nitrogen (nitrates and nitrites) were absent in every case.

[1] *Giornale della R. Accademia di Medicina di Torino*, anno lviii. fasc. 11, 32 pp.

Muntz and Aubin, as well as Boussingault, came to the same results from the analyses of the meteoric and telluric waters collected above or a little below 3000 metres. The absence of nitric and nitrous compounds in the waters of these heights is perhaps to be explained by the mean elevation of thunderstorms, which generally do not reach the 3000 metres in our zone, and to which the synthesis of those compounds from the elements of the atmosphere is mainly due. But many more accurate meteorological and chemical observations are necessary to confirm this hypothesis on a solid ground.

Among the interesting results of our expedition was the discovery of a substance having all the characters of the cryoconite as described by Nordenskiöld, who first discovered and named it. A fine, black, soot-like, light dust, lying at the bottom of lilipufian wells closely spread over the surface of the ice, was collected on the Garstelet glacier, and might perhaps be found on every flat ice-field whose surface is free from the impetuous little rivulets which wash and carry away everything that come in their way.

An immediate analysis of the cryoconite could not be made; I sealed the dust up on the spot in little glass bottles, which were opened later in my laboratory in Turin, when I found that putrefactive processes had taken place; gases, traces of skatol (or indol) together with a fatty (butyric?) acid had been formed, and the iron—which might have been originally in a metallic condition was dissolved as ferrous salt, showing the want of oxygen in the air of the bottle.

The presence of organic living matter in the cryoconite is confirmed by the results of an examination of the cryoconite made by Dr. Belli, of the Botanic Institute: he found in the cryoconite:—

Algæ: (Diatomaceæ). *Pinnularia* sp., *Navicula* sp., *Frustulia* sp. (?)
(Cyanophyceæ) *Oscillaria*, sp.
(Chlorophyceæ) *Pleurococcus* sp., *Chroococcus* sp., *Hematococcus pluvialis*, Kh.
Fungi (Bacteriaceæ) *Bacillus* sp., *Bacterium* sp.
,, (Ascomycetes) spores with echinated episporium, difficult to be determined.
Gymnospermæ—Pollen of Coniferæ (Abietineæ?)

Besides pappi of Compositæ (?) or of Graminaceæ or Cyperaceæ, threads or trychoms belonging to feathery seeds (*Salix*, *Epilobium*, *Clematis* (?).

Of the cryoconite 16 per cent. is organic matter, 3·5 per cent. iron, and the remnant detritus of different minerals.

A study of the distribution of micro-organisms in the ice and waters of Monte Rosa has also been made, and will be shortly published. Piero Giacosa.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. F. W. Burstall, Demonstrator of Mechanical Engineering at King's College, London, has been appointed Professor of Civil and Mechanical Engineering at Mason College, Birmingham.

The London University Commission Bill, which would have passed through the House of Commons this session if all parties had been willing to permit it, has been withdrawn, the Church party having claimed the insertion of a clause embodying a fragment of the Tests Act.

The action of the North Riding of Yorkshire in adding millinery to the list of technical subjects aided by the funds at their disposal, can hardly be commended. It was not for the purpose of teaching such empirical arts as this, that the Technical Instruction Acts were passed.

There does not seem to be a great demand for instruction in technical subjects in Cambridgeshire. At the recent meeting of the County Council a comparative failure of the lectures in agriculture had to be reported, and, following this, one member of the Technical Instruction Committee was understood to say that he supposed the money must be got rid of, but that he did not think it would do sixpennyworth of good! There yet remains much for the advocates of the teaching of natural science to do.

Among recent announcements we notice the following:—Dr. Schleiermacher to be Professor of Electro-technics in the Technical High School at Karlsruhe; Dr. Schuberg to be Extraordinary Professor of Zoology in Heidelberg University; Dr.

A. C. Abbott to succeed Dr. Billings in the chair of Hygiene in the University of Pennsylvania; Dr. Franz Hofmeister to succeed the late Prof. Hoppe-Seyler as Professor of Physiological Chemistry in Strassburg University; Prof. P. Jacobsohn to be General Secretary of the German Chemical Society; Drs. Josse and Kämmerer to be Professors of Engineering in the Technical High School of Berlin; Prof. Schmidt, of Stuttgart, to be Director of the Weather Bureau at Wurtemburg.

The Technical Education Committee, in their report to the recent meeting of the Nottinghamshire County Council, called attention to rather an unlooked-for difficulty which had presented itself in connection with their Dairy Institute. It appears that the butter made there is in such request that they had a demand for 1000 lbs. per week, and were actually producing as much as 500 lbs. in this period. The temptation is to convert the institute into a butter-factory, and so into a money-making concern; but the Council supported the Committee in their recommendation that it would be altogether inadvisable to sacrifice the educational interests of the institution to such pecuniary considerations, and that, as in the past, the first aim of the staff must be the instruction of the students.

It may be thought that the experimental stage in the administration of the Customs and Excise grants to education has been passed, but recent reports seem to negative this idea. The Lancashire committee report that they have been able to allot only eight out of ten science scholarships, the candidates showing a greater preference for the study of art. The Organising Secretary for the Lindsey division of Lincolnshire tells of 868 candidates for technical examinations this year as compared with 1012 last year. We hope that this does not mean that the novelty is wearing off, and that the serious demand for instruction of this kind is really less than had been anticipated. However this may be, there can be no doubt of the wisdom of the grant of £150 by this Council to the Nottingham University College for the year 1896-7.

At the recent general meeting of the Association of Directors and Organising Secretaries for Technical and Secondary Education the following resolutions were adopted: (1) "That, in the opinion of this Association, it is desirable to ask the Government to receive a deputation to urge upon them the importance of bringing in a Bill early next session dealing with the subject of Secondary Education." (2) "That it is inexpedient to give grants to any non-county borough for building or equipment except upon the terms that such grants shall be returned in the event of such borough becoming a separate educational authority." (3) "That this Association protests against the action of the Science and Art Department in making changes in its grants and regulations for the conduct of its classes without giving due notice to or consulting the local authorities who are so vitally interested in the efficiency of these classes, and particularly urges that the regulations contained in Form 306 be postponed until the issue of the Directory for 1897-98."

The Organising Secretary for Technical Instruction in the county of Shropshire, in reporting a diminution in the amount of work done in different parts of the county during the past session, observed that it "is ascribable to the vote of the Council in May 1894, by which the fund for technical instruction was reduced to the extent of £3000." This lessening of the grant has been more particularly felt in the towns where the best work was being done by science and art committees. The interruption of a systematic course of training is not, he finds, so serious in rural districts. The diminution complained of is the more to be deplored since already it has been found that the work of the Committee has been productive of practical results, particularly in the ornamental iron and tile manufactories and in the china works of the county. We notice that this Council has provided for the training at suitable institutions of six women as certificated midwives, and that the women have been selected with the view to their being able to follow the calling in parts of the county where there is most need for the services of such skilled nurses.

The County Committees in charge of technical instruction will do well to take notice of the letter received from the Science and Art Department by the Clerk of the Cornwall County Council, which decides a point of some interest. The letter, which is in reply to a query from the Clerk, runs as follows:—"I am directed to acquaint you that the Department, having already consulted the Local Government Board on the question of the provision of prizes by local authorities, is of opinion that the Cornwall County Council cannot properly apply funds placed at their disposal for the purposes of technical education to awarding prizes (through the medium of local committees) at competitions in agricultural processes to persons other than those who have been taught in classes under the control of, or aided by, the County Council." This decision will prove very salutary, we should think, in view of some of the claims which have been made; for instance, from some districts payments for luncheons, refreshments, ale, spirits, &c., have been demanded—things we should have thought nobody would have supposed connected with technical education.

SCIENTIFIC SERIAL.

Ciel et Terre of July 16 contains an article by M. A. Lancaster, of the Royal Observatory of Brussels, on the intensity of tropical rainfall. There are many points in that zone where the yearly rainfall exceeds 120 inches; such amounts clearly indicate more or less continuous falls of great intensity. The author quotes various excessive amounts observed in periods of twenty-four hours and less, but we extract only a few of the principal falls, reduced to a period of one minute and expressed in inches:—Hong Kong, ·047; Buitenzorg, ·049; Newcastle (New South Wales), ·071; Lahore, ·095; Brussels, ·114; London (Camden Square), ·167. These figures show that the falls of rain in the tropics are not more intense than the extraordinary falls in our own parts, but the former generally exceed the latter in duration; hence the much greater absolute quantity recorded in equatorial regions.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 3.—M. A. Chatin in the chair.—Study of the diamond-bearing sands of Brazil, by M. H. Moissan. From 4·5 kilos. of sand, only 2 gr. of material free from silica was obtained, and this was found to contain a small quantity of gold, platinum and graphite, together with a minute amount of diamond, partly black and partly transparent.—On the oxidation of the organic material of the soil, by MM. P. P. Dehérain and E. Demoussy. At temperatures slightly above 100° the organic material of soil is rapidly burnt by the oxygen of the air. This oxidation still goes on, without any organisms being present, at 40° to 60° C., and hence in hot climates the soil would become sterile from this cause.—On a hybrid from *Ovis tragelaphus*, by M. A. Milne-Edwards.—An extension of the application of the law of equivalence of energy in biology, by M. A. Chauveau.—Remarks on a note of M. A. Lœwy on definite quadratic forms, by M. L. Fuchs. The theorem in question is a special case of a theorem given in a memoir published in the *Sitzungsberichte* of the Berlin Academy.—The conditions under which the deposits of phosphate of lime have taken place in Picardy, by M. Gosselet. It is regarded as established that these phosphatic deposits were formed at very slight depths.—On the integration of simultaneous partial differential equations, by M. E. von Weber.—On a class of isothermal surfaces depending on two arbitrary functions, by M. A. Thybaut.—On the error of refraction in geometric levelling, by M. Ch. Lallemand. The formulæ given in a preceding paper are for practical purposes given in a graphical form.—On the non-refractibility of the X-rays by potassium, by M. F. Beaulard. A prism of potassium gave no appreciable deviation of Röntgen rays, the index of refraction differing from unity by a quantity less than 1/10,000.—Nitrogen and argon in fire-damp and in gas from Rochebelle, by M. Th. Schlœsing, jun. The gas left after removal of methane and carbon dioxide, consisting of argon and nitrogen, on absorbing the latter gave amounts of argon varying from 1·09 per cent. to 3·27 per cent. of the mixture. These figures show that this argon does not come directly from the air, but it is still possible that it may have come indirectly by solution in water, in which argon is the more soluble.—On the specific heat of sulphur in the viscous state, by M. J. Dussy. The specific heat of viscous sulphur is distinctly higher in the viscous than in the liquid state. If the total quantity of heat lost by 1 gr. of sulphur in passing from a temperature T to 0° C. is plotted against the temperature, there is a distinct change of curvature at about 230° C.—Contributions

to the analytical characters of the compounds of tungsten, by M. E. Defacoz. The tungsten compound is converted into a tungstate, heated with some $KHSO_4$ and a little sulphuric acid, and a drop of this, added to such reagents as phenol, naphthol, morphine, &c., when characteristic colour reactions occur. Of these the red coloration with phenol, and the violet with hydroquinol, are the most sensitive and distinctive.—On the action of aluminium chloride upon benzene containing thiophene, by M. Eyvind Boedtker. Hydrogen sulphide is evolved, and the bulk of the thiophene is destroyed.—On some new mixed trimethylene compounds, by M. L. Henry. The new substances described are α-iodo-ω-chloro-propane, $CH_2Cl.CH_2.CH_2I$; and the corresponding nitro-derivative, $CH_2Cl—CH_2.CH_2.(NO_2)$.—The rapid estimation of the constituents of a mixture of primary, secondary, and tertiary amines, having the same fatty alkyl group, by M. Ch. Gassmann. The mixture is titrated with hydrochloric acid, and then with sodium nitrite in acid solution; the solution of the resulting simultaneous equations gives results of sufficient accuracy for industrial purposes.—On the compounds oxidisable under the influence of the oxidising ferment of mushrooms, by M. Em. Bourquelot.—On the hybernation of the *Clavelina lepadiformis* (Müller), by MM. A. Giard and M. Caullery.—Treatment of experimental infections by intravenous injection of a solution of common salt (0·7 per cent.), and their mode of action, by MM. F. J. Bosc and V. Vedel.—On the nature of the "Chabins," by M. Ch. Cornevin. The Chabin (so-called by Gay) of Chili is not a hybrid, but a species of sheep.—Chemical study of low-class flour used in baking, by M. Balland.—On the proximate composition of the gluten of cereals, by M. E. Fleurent.

AMSTERDAM.

Royal Academy of Sciences, June 27.—Prof. van de Sande Bakhuyzen in the chair.—Mr. C. Eykman presented for publication in the Academy's *Transactions* a paper on the respiratory gas interchange of the inhabitants of the tropics. The principal result of the experiments made at Batavia with Geppert and Zuntz's apparatus, on persons in a state of rest was, that both the European and the Malayan inhabitant of the tropics, the weight of their bodies being reduced to the same standard, use the same quantity of oxygen, and consequently produce the same amount of heat, as the inhabitant of the temperate zones, to whom the same test has been applied. Moreover, the ratio of the quantity of carbonic acid exhaled to that of oxygen inhaled by Europeans, is pretty much the same in India as in Europe; with Malayans the amount of carbonic acid exhaled is comparatively a little greater, which is accounted for by the food of the latter being richer in carbohydrates.—Prof. van Bemmelen communicated the result of an investigation into the proportion of fluorine in the fossil bones from the Pliocene formation in Middle-Java (Dubois' collection), which proportion was determined by the author in co-operation with Mr. Klobbie. He also treated of the coefficient of distribution in the absorption of dissolved substances by colloids.—Prof. van de Sande Bakhuyzen dealt with the determination of the error of projection in the case of Repsold's instrument for measuring photographs of stars.—Prof. Kamerlingh Onnes presented a continuation of his observations on the measurement of low temperatures.—Mr. Verschaffelt described measurements of capillary ascents of liquid carbon near the critical temperature. In his thermodynamic theory of capillarity, Prof. van der Waals has calculated, on theoretical grounds, the surface energy of a liquid near the critical temperature. He arrives at the conclusion that, at least if the temperature is very nearly critical, it must be possible to represent the surface energy by the formula, $\sigma = A(1-m)^{3/2}$, in which A is a constant, and m the reduced temperature. The values of σ, deduced from experiments made by de Vries, and by Ramsay and Shields, may now be represented by a formula $\sigma = A(1-m)^B$, in which B is generally constant and smaller than 3/2, though in a few cases it gradually increases, in proportion as the critical point is approached. It was, therefore, desirable to measure some ascents, when the temperature was still nearer the critical point; and liquid carbonic acid was selected for this investigation. Up to 30° the change of the height of ascent is pretty nearly linear; for a capillary of a radius $r = 0{\cdot}0441\ m$M, it was found that

$$HmM = 26{\cdot}04 - 0{\cdot}825\ t.$$

As this line cuts the temperature axis at 31°·6, and as the critical point, where H must be = 0, was found to be 31°·0, the "height-of-ascent" curve must incline a little towards the temperature axis between 30° and 31°, which was actually observed. For the calculation of the surface energy the liquid and gas densities determined by Amagat were used. Cailletet and Mathias have constructed parabolic formulæ for those densities, from which follows, it would seem, $\int v - \int d = k\sqrt{1-m}$. According to van der Waals this relation must be theoretically satisfied, at least near the critical temperature. When the quotient

$$\Delta \log \left(\int v - \int d\right) / \Delta \log (1-m)$$

is now deduced from the densities, given by Amagat, then it appears that up to about 30° it remains pretty nearly constant, the mean being 0·367, consequently smaller than the value derived from Cailletet's and Mathias's formulæ; above 30° it rises and reaches the value 0·521, in accordance with the theory. As regards $\Delta \log \sigma / \Delta \log (1-m)$, which, according to van der Waals, must become equal to 1·5 in the immediate proximity of the critical temperature, the calculation shows that this quotient becomes smaller up to 29°, but then it increases again, the maximum found being 1·512.—Prof. Engelmann communicated the result of investigations into the origin of the normal movement of the heart, from which it appears that very probably it is not of a neurogenic, but of a purely myogenic nature.—Prof. Franchimont presented, on behalf of Dr. P. van Romburgh, of Buitenzorg, a paper on the action of iodine upon potassium cyanide, and of iodine cyanide upon caustic potash, in which it is proved that the opinion that iodine cyanide behaves differently from potassium, from bromine- and chlorine-cyanide, is founded on an error, which has probably originated in not awaiting the end of the reaction, on making the experiments. After twenty-five minutes the final products are: at 25°, potassium isocyanate and potassium iodide; they are also obtained by adding iodine to an alkaline potassium cyanide solution, when for a moment the smell of iodine cyanide is observed. The concentration seems not to have any influence upon the result, but it has upon the rapidity of the reaction.

A SYSTEM OF MEDICINE.

A System of Medicine. By many Writers. Edited by Thos. Clifford Allbutt, M.A., M.D., F.R.S., Regius Professor of Physic in the University of Cambridge, &c. Vol. i. Demy 8vo, pp. 1008, 38 illustrations, 13 charts, 1 coloured plate. (London: Macmillan and Co., Ltd., 1896.)

IT is almost exactly thirty years ago since the first volume of the "System of Medicine," edited by Sir Russell Reynolds, was published; and the dedication of the present work to him is a touching acknowledgment, on the part of the editor, of the service rendered to medicine by the late lamented President of the College of Physicians, and his band of collaborators. Thirty years has produced not only great changes in medicine itself, but also great changes in the methods of attacking medical problems. The intimate relation in which medicine to-day stands to what may, perhaps, collectively best be termed experimental pathology, has rendered necessary in the present System, the collaboration of a band of authors whose names are better known as physiologists, pathologists, or bacteriologists than physicians, and their contributions lend a very special value to the work. The book begins with an academic introduction by the editor, who at once rightly denies any corporeal fixity to the term "System of Medicine," and defines it as "a setting forth of the whole of our knowledge, as immediate convenience and the exigencies of contemporary learning may dictate." A few brief but pregnant remarks upon classification, nomenclature, diagnosis and prognosis, lead us to Division i. of the System, which has received the name of prolegomena. Each of the articles, twenty in number, contained in this part of the work is complete in itself, and may be regarded as representing the present state of our knowledge upon the subject of which it treats.

Medical Statistics are dealt with by Dr. Billings in a most able and exhaustive manner; Anthropology and Medicine by Dr. Beddoe. Dr. Rivers, in a short essay on Temperament, points out that a valuable classification of temperaments may be expected from a study of this subject on the lines of Galton and Kraepelin. Mr. Hutchinson, in a few pages, discusses "The Laws of Inheritance in Disease." Dr. Haviland tells us succinctly what is known with regard to the relations of the physical geography of this country to heart disease, cancer and phthisis.

One of the most difficult tasks in the book has fallen to the lot of Prof. Adami, who contributes the monograph on Inflammation. The article is divided into three parts. Part i. is devoted to the comparative pathology of inflammation; chapter i. is introductory; chapter ii. contains an account of the researches of Metschnikoff, Krukenberg, Reinke, and others, on the effects of irritants on the protozoa and lower metazoa; chapter iii. describes the main forms of the process of acute inflammation in the higher animals, in which the experimental production of suppurative inflammation finds a place. Here the author considers at length the work of Cohnheim, Grawitz, and De Barry, Councilman, and others. Part ii. is devoted to the factors in the inflammatory process considered in detail, and first and foremost the part played by the leucocytes. The author here gives, with a table, a classification of leucocytes according to the different authorities. The rival theories of "phagocytosis" and "extra cellular action" are discussed at length. Dr. Adami inclines to the view that although different bacterial products may give rise to positive chemiotaxis of varying intensity, the possession by these products of actual negative chemiotactic properties is very doubtful. The author concludes by saying that however important phagocytosis may be to the organism, the extra-cellular action of active and disintegrating leucocytes may under certain conditions be even more so. The question of the inflammatory exudation, the part played by the vascular and nervous systems, the diapedesis of the leucocytes, which the author regards as active, and caused by the positive chemiotactic properties of the irritant, are each considered. Of the *rôle* played by the cells of the tissues, and of the origin of the "fibroblasts," a full account is given; and this part of the subject concludes with an exhaustive chapter on the varieties of fibrous hyperplasia and their relation to inflammation. Part iii. is devoted to classification and the systemic changes consequent upon inflammation. The author, in conclusion, defines inflammation as "the local attempt at repair of actual or referred injury." In the article just considered, Prof. Adami has certainly accomplished the task he set before himself, viz. "to bring into order the very numerous recent researches upon the inflammatory process, and to show whither they appear to tend."

The Doctrine of Fever is dealt with by Dr. Burdon Sanderson, and divided into two parts. Part i. is a historical retrospect which deals chiefly with the views of Cohnheim, Senator, Traube, Pfluger, and Leyden. Part ii. gives an account of the researches bearing on this subject since 1883. The relation between the increased proteid disintegration in fever and in inanition is discussed, as is the production of "fever," so called, by cerebral puncture and the mode of action of antipyrine and other antipyritics.

An article on the General Pathology of Nutrition is contributed by Dr. F. W. Mott. Dr. Mott first describes the physiology of nutrition, and discusses the influence of the quality of the blood, the internal secretions of the organs, the nervous system, and the inherited specific properties of the blood, upon the maintenance of a normal state of nutrition. Necrosis, atrophy and fibrosis, the degenerations, and hypertrophy are fully dealt with. The author holds the view that in the fatty degeneration of myelin, lecithin is the source of the fat, and suggests that extensive degeneration of this kind may produce an auto-intoxication. The article is well illustrated. A monograph on the General Pathology of New Growths is communicated by Messrs. Shattock and Ballance. The chief interest of this article lies in the full description and searching criticism of the parasitic theory of carcinoma. The authors have spared neither time nor trouble to put this theory to scientific tests. All attempts to cultivate the hypothetical parasite of carcinoma, either directly in various media or through the intervention of lower forms of life, were negative. The treatment of

carcinoma and sarcoma by injection of a glycerine extract (50 per cent.) of the respective growth, was also without result, as was also treatment with Fehleisen's fluid.

The Principles of Drug Therapeutics are considered by Prof. Leech. Dr. Herman Weber, assisted by Dr. M. G. Forster, writes upon Climatology. The article comprises a consideration of some of the principal elements of climate, the chief climatic regions and health resorts, and the use of climate in the treatment and prevention of disease. The essay on Balneology and Hydrotherapeutics is from the same author, and is divided into two parts: (A) balneo-therapeutics, or treatment by the internal or external use of mineral waters; under this section the chief mineral waters are described, and their therapeutic use indicated. The second (or B) section is termed hydrotherapeutics: by this is meant the therapeutic use of water considered especially in its external application to the body; in this section the author is assisted by Dr. Parkes Weber. Artificial Ærotherapeutics is treated by Dr. Theodore Williams, the varieties of qualitative and quantitative differences in the constituents of the atmosphere are described, as are also the effects of atmospheres of varying barometric pressure. Dr. Lewis Jones writes upon the Medical Applications of Electricity. The units of measurement are explained, and the apparatus necessary for the application of electricity described. Six excellent diagrams of the motor points in the different parts of the body are given. The diagnostic use of electricity is fully discussed. The article closes with a consideration of the conditions in which the medical application of electricity has been of therapeutic value. Dr. Mitchell considers the technique, physiology and therapeutic uses of Massage. Under the head of physiology a *résumé* is given of the work of Lombard, Brunton and Tunnicliffe, Winternitz, and others. The varieties of massage, the duration and frequency of its application, are described, and the diseases in which massage has been useful enumerated. The Feeding of the Sick is the subject of an article by Sir Dyce Duckworth. The general principles of invalid dietetics are first clearly enunciated, and then all the experience of the clinician is brought to bear upon the subject of the diets suitable to various diseases. A most valuable addition to this subject comes from the pen of Dr. Eustace Smith, who writes upon the Diet and Therapeutics of Children. The very special way in which children react to different diets and forms of treatment, baths, drugs, &c., is described, and the way to obtain a maximum benefit from the remedies prescribed is clearly indicated. The editor has wisely included an article on Nursing, which is written by Miss Amy Hughes. The Hygiene of Youth is treated by Dr. Clement Dukes, in a paper which it would be well to place in the hands of every schoolmaster. The medical aspect of Life Assurance is considered by Dr. Symes Thompson. With this article Division i. of the work closes.

Division ii. is devoted to the consideration of the Fevers, and includes two parts. Part i. consists of an article from the pen of Sir Joseph Fayrer, on Insolation or Sunstroke. The Infections form the contents of Part ii. The subject is introduced by an article on the general pathology of infection, by Dr. Kanthack. The Infections are then divided as follows: (1) diseases of more or less established bacteriology, (2) diseases of uncertain bacteriology, (3) infective diseases communicable from animals to man, (4) diseases due to the protozoa. The first group is divided into local or general diseases due to pyococci, and the infective fevers, with which the volume ends.

Dr. Kanthack, in his article on the general pathology of infection, first considers the morphology of micro organisms and the conditions necessary for their existence; he then passes on to the products of bacterial activity. Ferments and enzymes, the ptomaines, toxalbumins, and the products of fermentation are fully discussed. The question whether the toxines are the result of the action of the bacilli on the tissues (Martin), or whether they are a true excretion or secretion of the bacilli themselves, is discussed, as are also the views of Klein on extracellular and intracellular poisons. A consideration of infection, contagion, and predisposition follows. The author then proceeds to the subject of natural and acquired immunity, and the article concludes with the history, principles, methods, and scope of serum therapeutics. Two admirable monographs on septicæmia and pyæmia, and erysipelas, are written by Mr. Watson Cheyne. The ætiology and general pathology of ulcerative endocarditis is dealt with by Dr. Dreschfeld; Puerperal Septic Disease by Dr. Playfair. The articles on boils and carbuncles are written by Dr. Melsome, that on Epidemic Pneumonia by Dr. Whitelegge. Epidemic cerebro-spinal Meningitis is considered by Dr. Ormerod, who adds an appendix describing the outbreaks of the disease in this country since 1807. Dr. Goodhart writes upon influenza. The article includes a description of Pfeiffer's bacillus, and the methods for its identification and cultivation. The article on Diphtheria is divided into four parts. The clinical aspects of Diphtheria are dealt with by Dr. Gee, its ætiology and prophylaxis by Dr. Thorne Thorne, its bacteriology and pathology by Dr. Kanthack, while Dr. Herringham gives the results of the serum treatment. The subject of Tetanus is also divided between two authors—Sir G. Humphrey contributing the clinical part, Dr. Sims Woodhead the pathological. The relatively unfavourable results of the antitoxine treatment in this disease, as compared with those in Diphtheria, are explained by Dr. Woodhead as being due to the fact that the treatment in tetanus is not begun until the effects of the poison on the general system (central nervous system), as distinct from its local effects, have manifested themselves; whereas in Diphtheria, the antitoxine is injected at a period at which the disease is practically a local one. Enteric Fever is treated in an exhaustive manner by Dr. Dreschfeld. The article contains a description of Eberth's bacillus, with the characteristics distinguishing it from the *B. coli communis*, and the methods for its detection. Extensive mortality tables form an appendix. Five authors are responsible for the article on Asiatic Cholera. Mr. Ernest Hart and Dr. Smith deal with the origin and mode of propagation of the disease, Drs. Kanthack and Stephens with the bacteriology, and Dr. Kenneth Macleod with the clinical, pathological, and therapeutical aspects of the subject.

The Plague is treated by Dr. Payne. The bacteriology of the disease, in the light of Yersin and Kitasato's researches, is fully discussed, and the possibility of treatment by antitoxine (Calmette). Relapsing Fever is dealt with by Dr. Rabagliati; the bacteriology of the subject being from the pen of Dr. Westbrook. With this last article Volume i. closes. At the end of each monograph there is a list of references, which are paragraphed, according to the sub-section of the article to which they refer. An accurate and extensive index of authors and subjects greatly facilitates the use of the book.

An idea of the labour requisite to the successful editing of a work like the one before us can only be formed by the experienced few who have accomplished it. To Prof. Allbutt are due the thanks and congratulations of cosmopolitan Medicine for having produced a work which in fulness, accuracy and interest, leaves nothing to be desired. F. W. T.

A TEXT-BOOK OF EXPERIMENTAL PHYSICS.

Lehrbuch der Experimental Physik. Von Eduard Riecke. Erster Band. Mechanik, Akustik, Optik. Pp. xvi + 418. (Leipzig: Verlag von Veit and Co., 1896.)

THE author, who is Professor of Physics in the University of Göttingen, is well and favourably known for his work in several departments of physical science, and the text-book he has written possesses the qualities we should expect to find in the work of one who is actively engaged not only in teaching physics, but in advancing the subject by research.

After an introduction on physical phenomena, physical hypotheses and theories, and elementary measurements such as those of angle, length, mass, and time, the treatise enters on the subjects of mechanics and acoustics, to which the first part of the present volume is devoted. This occupies pp. 20–261, leaving pp. 262–418 for the discussion of optics.

In opening his dynamical treatment, the author does not attempt to deal with the vexed questions of the foundations of dynamics, a procedure which is perhaps the best in the interests of beginners. The thoughtful student will be confronted with the fundamental difficulties soon enough, and according to his own ability and the skill of his dynamical adviser will be his relief from the serious mental embarrassment which he will inevitably experience. The thoughtless student need not be considered.

The author postpones the consideration of mass, and defines the unit of weight as the weight of a cubic centimetre of distilled water at maximum density under atmospheric pressure, which he calls a *gramme-gewicht.* We differ from the author as to this being the *definition* of the unit of weight in the metric system. Surely that unit is the weight of the standard kilogramme itself, or of $\frac{1}{1000}$ part of it. By the statement given the unit of weight is not immediately connected with the standard piece of matter; though it is no doubt very nearly $\frac{1}{1000}$ of the weight of the standard kilogramme. The unit of weight is, however, made the weight of a unit of mass, and is therefore, strictly speaking, a variable unit; it is used throughout the treatment of the statics of rigid bodies, with which the dynamical portion of the book begins.

The method adopted thus differs from that now usually followed, in English books at least, by considering a vertical string or bar which supports a body as stretched by a force equal to the weight of the body, as measured by the number of cubic centimetres of distilled water at maximum density which will just equilibrate the body in an accurate balance. Thus, so far as statics is concerned, a preliminary kinetic definition and discussion of force and the laws of motion are dispensed with.

Whatever opinion may be held as to the merits or demerits of this mode of presenting the subject of statics, there can be no question of the importance of referring the student on every possible occasion for illustration of principles and theorems to the great practical applications of dynamics that we have in abundance in engineering structures, and of the use where possible of graphical methods. This is an aim which the author keeps well in view, though in order to proceed to the consideration of stretching force and thrust, and ties and struts, it does seem a little hasty to dismiss the parallelogram of forces with a mere experimental proof by means of strings and weights.

The discussion of the kinetics (*dynamics* the author calls it) of solid bodies follows. This has many points of excellence. But we must rather demur to the comparison of the absolute and technical units, given at p. 67. Thus it is stated—

Absolute.	*Technical.*
Unit of mass equal to the mass of a gramme.	Unit of force equal to the weight of a gramme at latitude 45°.
Unit of force equal to the weight of $\frac{1}{981}$ gramme at latitude 45°.	Unit of mass equal to the mass of 981 gramme weights.

Whatever the somewhat disputed relative merits for different purposes of the absolute and technical system of units may be, it is universally admitted that the absolute C.G.S. unit of force is that force which gives a mass of one gramme an acceleration of 1 centimetre per second per second. To define it, or state its value as above, is to give no doubt a constant unit of force (on the supposition that gravity is constant at latitude 45°), but one differing perceptibly from that usually defined as the absolute unit, since the value of g at latitude 45° at mean sea-level is approximately 980·61 in centimetre second units. The great beauty of the absolute system as given by Gauss, surely lies in the fact that the fundamental units of length, mass, and time do all for us, and we have, so far as the *definition* of dynamical units is concerned, nothing whatever to do with gravity.

The proper definition of the unit of force it must be stated, however, is given *below* this "Gegenüberstellung" of units, so that the author probably does not offer the statement in the table as other than a comparison of values of units; but it is well to give first the definition, and rub it in with plenty of illustration. Only after the student has become perfectly familiar with the system of

units he has been introduced to, is it safe to bring another under his notice.

Many interesting cases of motion are well expounded and illustrated by diagrams, for example the motion of a pendulum with a gyrostat in its bob (a case of great importance in other branches of physics), and the precession of the equinoxes.

The statics and kinetics of fluids are next dealt with, and, as was to be expected, fluid motion is well attended to. Wave motion of a fluid and the principle of Huyghens are here discussed and well illustrated graphically. Then follows a wonderfully complete account, for the space devoted to it, of molecular phenomena of solids and fluids, including a sketch of the kinetic theory of gases.

The second half of the book, which deals with acoustics and optics, we have not space to speak of in any detail. Throughout we have clear description of phenomena, of apparatus, and of experimental processes, always with neat and truthfully-drawn diagrams. There is necessarily very little in the way of mathematical exposition of these subjects, but the results of mathematical and experimental investigation are clearly stated, and the book cannot but form an exceedingly useful introduction to an extended course of physical study, such as that for which one of the more elaborate Lehrbücher, which have lately appeared in Germany, might form a basis. It is very clearly printed, and, what is a great thing in a text-book, the numerous cuts have been very well engraved and printed.

A. Gray.

TRAVELS AMONG THE HAUSA.

Hausaland, or Fifteen Hundred Miles through the Central Soudan. By Charles Henry Robinson, M.A. Pp. 304. Map and illustrations. (London: Sampson Low, Marston, and Co., 1896.)

Mr. J. A. Robinson, the brother of the author of the book before us, died at Lokoja on the Niger in 1891, while engaged in the study of the Hausa language, and in his memory the Hausa Association was formed in the same year with a view to carry on the work. Mr. C. H. Robinson was selected by the Association as their first "Hausa Student," and he left England at the end of April 1893, to make acquaintance with the language, and also to learn Arabic. Instead of proceeding directly to the land of the Hausas, the climate of which at the best is very trying for Europeans, he went successively to Tripoli and Tunis, where he had opportunities of conversing with many of the Hausa pilgrims on their way from the interior of the Sudan to Mecca, and with any number of Hausa slaves.

Equipped by preliminary training in the language, and accompanied by two friends, Dr. T. J. Tonkin and Mr. John Bonner, Mr. Robinson reached Lokoja, at the confluence of the Niger and Benue, in August 1894; and, after wearisome delays in obtaining carriers, set out for Kano, the commercial capital of the Hausa states. They travelled up the Benue to Loko, then struck northwards by land through Kaffa and Zaria, and reached Kano on December 23. Here the party stayed for rather more than three months, engaged in diligent study, and then returned to the Niger and to Europe.

Hausaland is not a defined geographical area, but a group of native states occupying the fertile region of the Western Sudan between the territory of the Royal Niger Company (to which they are tributary) and the Sahara desert. Sokoto is the predominant state, but the chief town of the Hausas is Kano, a trade-centre of such importance that Mr. Robinson does not hesitate to dub it the "Manchester of the Soudan." The town is described in some detail, and this description is perhaps the most important feature of the book, which in other parts suffers from "padding," including long extracts from various writers on non-essential subjects. Kano is estimated to contain about 100,000 inhabitants; it manufactures much cloth, which is largely exported, and may be purchased in Alexandria, Tunis, or Lagos, so widely are its qualities appreciated. The markets also contain European goods, which are still, for the most part, brought across the Sahara from Mediterranean ports. The Hausas are born traders, and having acquired Mohammedan education, are by no means to be viewed as savages. They are, however, inveterate slave-traders; and Mr. Robinson is of opinion that this trade cannot be seriously combated until a satisfactory currency and mechanical means of transport are introduced. At present slaves are the larger, and cowries the smaller, units of value; and as a slave is worth several hundred thousand cowries, the carriage of his value in these shells would tax the resources of any caravan. There is one coin which passes current through the whole of Northern Africa—perhaps the last in Europe which would occur to any one set to guess its nationality and date—the silver Austrian thaler coined in 1780 during the reign of Maria Theresa. Mr. Robinson urges a large importation of these coins as a measure to promote trade and discourage slavery. He has shown himself to be a diligent student and a good observer, although a somewhat diffuse writer, and the suggestion is worthy of consideration.

In the preface we are told that the Royal Geographical Society's system of spelling place-names has been followed; but this is only done in part. The French transliterations are used in some cases, and also other forms—as, for example, Abutshi, Bornou, Gandja, Soudan, Tchad; where the system referred to would require—Abuchai, Bornu, Ganja, Sudan, Chad.

It is to be hoped that the efforts of the Hausa Association will not be allowed to cease for want of money; for Mr. Robinson's linguistic work is of real value, and its importance will appear more fully when the facsimiles and translations of the Hausa MS. which he has brought home, together with his dictionary and grammar of the language, are published.

OUR BOOK SHELF.

Practical Mechanics, applied to the Requirements of the Sailor. By Thomas Mackenzie, Master Mariner, F.R.A.S., &c. Pp. xii + 175. (London: Charles Griffin and Co., Ltd., 1896.)

This book is one of a very useful series on nautical subjects, published in order to meet a desire on the part of the officers of the Mercantile Marine to obtain a more scientific insight into the principles of their profession.

It is becoming more generally recognised that the really "practical" man is the one who combines practical knowledge and experience with intelligent appreciation of underlying principles.

The aim of the book is to lay before sailors, in an easily comprehended manner, the principles on which the various mechanical devices employed by them are founded.

A large amount of useful information has therefore been gathered together in the small compass of this book, and rules and principles whose *general* application is explained in various text-books on practical and applied mechanics, are here specially adapted to the requirements of the sailor. To mention a few instances: we find explanations of the mechanical advantage gained by the various tackles and purchases; the construction of derricks and shears, and the weight they will support; the relative strengths of ropes; the breaking strains of spars; the floating power of spars and casks, and the weight which a raft, constructed of given materials, will bear; the effect of the wind on the sails in driving the ship ahead and in causing leeway; the effect of the water on the rudder; the extra strain thrown on slings when a ship is rolling, &c.

The principles of the composition and resolution of forces, and of the mechanical powers are somewhat fully explained in the opening chapters, and the idea of applying the traverse table, so familiar to all sailors, to the solution of the problems, is an excellent one; but more explanation of some of the rules given later, which have to be taken for granted, could be desired, as it is very difficult to retain bare rules in the memory.

The size of the book no doubt imposed limits on the amount of space to be devoted to explanation, but it provides, nevertheless, an excellent book of reference; and though it may not be necessary to make some of the calculations referred to, it is always useful to know how things are worked, and on what principles, and that the principles are in accordance with well-known physical laws. "A sailor is so often thrown on his own resources, and the more exact his knowledge is of natural forces, the more readily can he avail himself of the forces at hand."

The book contains several valuable tables, and a useful collection of rules in mensuration.

F. C. STEBBING.

Power Locomotion on the Highway. By Rhys Jenkins, M.I.Mech.E. Pp. 64. (London: William Cate, Ltd., 1896.)

THE sub-title of this publication sufficiently expresses the character of the contents; it is "a guide to the literature relating to traction engines and steam rollers and to the propulsion of common road carriages and velocipedes by steam and other mechanical power, with a brief historical sketch." The historical sketch is a concise statement of the lines along which progress in power locomotion on common roads has proceeded. Following it is a bibliography of works on mechanical carriages and traction engines, a catalogue of papers read before, or appearing in the Transactions of, scientific and technical societies, indexed under names of authors, a list of journals devoted to the mechanical carriage movement, and an index to articles on the subject in periodical literature up to the end of 1895. The periodicals indexed include those of the United States, France, and Germany, as well as of Great Britain. The author has evidently been at considerable pains to prepare his descriptive index, and his efforts deserve encouragement. It would be an immense boon if indexes of the same description were available for other branches of technology. The reception afforded to this little book will show whether the demand is sufficient to justify the publication of others of a like kind.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I REGRET very much that I did not correctly remember, when writing to NATURE a month ago, what my friend Mr. Thiselton-Dyer had said at the Linnean Society's meeting. I suppose that in consequence I must not greatly complain that whilst telling us what he really did say, my friend has taken the opportunity to present a version of my views which is far from accurate. He has less excuse than I had in attempting to cite his remarks, since he has before him my printed letter of July 16. This fact also renders it easy to show wherein he is inaccurate.

I suppose that we are all agreed that it is in the highest degree interesting to know what Mr. Darwin himself thought and said on questions of the kind now under discussion. At the same time, we are none of us, I imagine, likely to attribute to Mr. Dyer a special knowledge either of Darwin's writings or of their interpretation which we do not share. Naturalists are, I believe, not prepared to accept any individual as the authoritative exponent of Mr. Darwin's teaching. Under these circumstances it is to me a matter for regret that a plain discussion of the question whether specific characters are invariably useful should be turned into a dispute as to whether the person who suggests some special application of Mr. Darwin's doctrines, or advances some subordinate hypothesis in relation to their application, can or can not be solemnly regarded as an Orthodox Darwinian. Mr. Dyer says that the Darwinian theory seems hardly to have a convinced supporter left except Mr. Wallace. He denounces my quotations from Mr. Darwin's own books as to correlation of variation as a "difficulty" brought up by me "against" the Darwinian theory; then, without more ado, assumes the *rôle* of apostle of the Darwinian theory (a part to which I cannot allow him any exclusive claim), and proceeds to tell us what "will" be found in the twenty-fifth chapter of Mr. Darwin's "Animals and Plants under Domestication," viz. that Darwin has said pretty much all that can (as yet) be said about the facts of correlation of variation. The attempt on Mr. Dyer's part to represent my citation of Mr. Darwin's own conclusions in regard to correlation of variation as unorthodox, is a little beside the mark. No one is ignorant that it "will" be found that in the chapter cited Mr. Darwin discusses "correlation"; not only that, but it *has been* so found long ago and repeatedly by many other readers besides Mr. Dyer. I expressly stated, both at the Linnean Society and in my letter printed in NATURE on July 16, that I was quoting from Mr. Darwin both as to Wells and as to other instances.

Perhaps the most unsatisfactory feature in Mr. Dyer's claim to classify his friends as heterodox and orthodox in regard to Darwinism, is that it leads him to undertake to give away the Darwinian theory. "I frankly admit," he says, "that such a case [a case of correlated variation such as that hypothetically stated by me] if completely established would give the utility of specific characters, and with it the Darwinian theory, a serious blow." I do not value this frank admission. If Mr. Dyer feels constrained to admit to some one that such a case would give a serious blow to the Darwinian theory, he must not come to me with his "admission" of a "point scored"; for I neither admit that any such blow is given, nor can I accept Mr. Dyer's good-natured offer to act as representative of the Darwinian theory. All that my friend can represent in this matter is the Dyerian theory of Mr. Darwin's theory. Mr. Darwin never asserted in so many words that specific characters are invariably "useful," and in my judgment he did not hold that opinion. But whether he did or did not, that opinion can not, I think, be shown to be a necessary outcome of the theory of natural selection, provided that we take into consideration important ascertained properties of living matter. My impression is that Mr. Wallace—whom Mr. Dyer has declared to be the only convinced supporter of the Darwinian theory now left—stated at the Linnean Society that he agreed with me as to "correlated variation" sometimes accounting for a specific character which accordingly could not be regarded as due to utility. Such also I gathered was the view of Mr. Meldola. Yet neither of these gentlemen regarded this conclusion as a serious blow to the Darwinian

theory. Nor do I; on the contrary, I regard it as an important aid to the general application of the Darwinian theory.

Apart from the objection, which I have above expressed, to the treatment of this question by Mr. Dyer as one of orthodoxy, I note with regret that he has (unintentionally no doubt) misrepresented what I have actually said in my letter. Whereas I have expressly cited Mr. Darwin's principle of "correlation of variations," Mr. Dyer writes of the "extended correlation principle of Prof. Lankester." This form of pleasantry could be itself extended, but more of it would be unworthy of your pages. As a matter of fact, what I said as to correlation was very little more than a citation of cases and their theoretical explanation given by Mr. Darwin. To represent this as in any way parallel to the independent and anti-Darwinian theories of Mr. Romanes and Mr. Bateson, as is done by Mr. Dyer, is misrepresentation. The theory of Wells as to the black races of the tropics was used by me in order to illustrate my suggestion as to correlation leading to a development of useless specific characters. I might, equally well for my purpose, have used any of the other cases collected by Mr. Darwin. Whilst I spoke of Wells' case as "striking and suggestive," I at the same time expressly referred to it as "a more or less hypothetical case." Mr. Dyer has no justification, so far as I can see, for stating that I use this case as a foundation for wide generalisation. I made no wide generalisation, but adduced the wide generalisation at which Mr. Darwin, after collecting and considering a large variety of cases, arrived, viz. that correlation of variation does occur largely and generally in the organic world. This wide generalisation is, I say, not mine; it is Mr. Darwin's. If this generalisation be accepted—and we may reasonably hope that the apostolic and orthodox do accept it—then it seems to me in the highest degree probable that an obscure specific difference of structure—highly effective as life-preserving or progeny-ensuring—will more or less frequently carry with it as a correlated variation a more obvious and measurable character in some remote part of the body, not effective, that is to say, not useful. Hence I conclude that there may be specific characters (not by any means all or always) which are not themselves *useful*, though readily observed. That is the whole of my contribution to the present discussion. It does not seem to me to involve anything rash or surprising, though such is its character according to Mr. Dyer.

I may remind the readers of NATURE that some years ago, in these columns, I adduced this same principle, viz. Mr. Darwin's principle of correlation of variations, as one sufficient to remove some of the difficulties in the way of the doctrine of natural selection brought forward by the Duke of Argyll. What the Duke called "prophetic germs" might, it seemed to me (and still seems to me), when not explicable as lapsed rudimentary structures, be accounted for as variations or new structures correlated with other useful and therefore selected variations, although not yet themselves useful. A useless variation correlated with a useful one must (it seems to me) be supposed to pass through initial stages in which it is too small, or otherwise insignificant, to be useful (its utility or harmfulness being swamped in the utility of the correlated useful character), and only after attaining considerable development becomes either useful or harmful, and therefore subject to selection, possibly under some slight change of environment.

I regret all the more my differences with my friend Mr. Dyer, because the explanations they have involved leave me so little space in which to refer to Prof. Weldon's courteous and interesting letter. I have only one point to correct in his statement of my position in relation to that taken by him. The attempt to reconcile the *dicta* of Hume or Kant, or even of Mill, with the experience and approved practice of those who make it their business to investigate natural phenomena, would be an interesting undertaking, possibly one beyond the powers of living man. It is certainly not one upon which I shall here and now embark.

The point whereon Prof. Weldon has misunderstood my contention is this. After describing a phenomenon (death-rate) preceded invariably by two or more phenomena of structure or function, he says: "Under these circumstances, Prof. Lankester thinks it legitimate to pick out one of these antecedent phenomena and to speak of it as the only effective cause of change in death-rate, the other phenomena, although equally universal, being merely unimportant concomitants of this one essential change." Prof. Weldon is mistaken in stating that I think it legitimate "to pick out" without qualification, or at haphazard, any one of these antecedent phenomena, and to speak of it as the only effective cause. I should object to such a proceeding on much the same ground as that on which I object to his calling "any and all" of those antecedent phenomena effective causes.

What I think is the reasonable course in such a case—supposing that a man wishes to ascertain, as fully as may be, the relation of these phenomena to one another, is that he should frame in his mind a hypothesis as to how any one or more of the phenomena, invariably associated with a given death-rate, can operate so as to effect an increase or decrease in that death-rate. This, no doubt, will require a large knowledge of the surrounding conditions not usually to be acquired with ease, and an analysis of the antecedent phenomena in question, often of a prolonged and laborious character. Sometimes, however, such a hypothesis will present itself very readily and with much antecedent probability. However attained, the hypothesis will remain merely a guess until it is tested. It can be tested either by experiment or by observation of appropriate natural instances. By repeated testing, involving often great ingenuity and prolonged labour, the hypothesis is either confirmed or discarded; possibly a new hypothesis is adopted, so to speak, *en route*, and established as in all probability true. When—and not until—this process has been gone through, the naturalist will be, more or less according to the extent of his work, in a position to *place* the phenomena in their true relation to one another and to the ultimate phenomenon proposed for investigation, viz. death-rate. If the study of the antecedent or associated phenomena by means of hypothesis and test-experiment has not been and cannot be carried out, the naturalist can not (it seems to me) reasonably either "pick out" one of them and assert that it is the cause of increased or decreased death-rate, nor (still less) declare that all the antecedent or associated phenomena are the causes and produce the effect of increased or decreased death-rate. If he does do so, he appears to me to be evading the task before him, which is to "explain," that is, to place in their true order and relation a complex group of related phenomena.

The appeal to analogy no doubt frequently leads naturalists to rapid conclusions as to the causal relations of the phenomena of organisms. Often (but by no means always) such conclusions are erroneous: but it is not on that account desirable to reject the argument from analogy in reasoning about such matters. It must be used with knowledge and with caution. It seems to me, that in considering a complex case in which actual experiment is as yet wanting, it is often more useful to formulate provisional conclusions as to what is cause and what only concomitant effect by the aid of argument from analogy, than to deliberately reject all attempts at analysis, and to "lump" all the constantly associated phenomena as "causes." Surely in the case of Prof. Weldon's crabs, most naturalists would take the view that the frontal measurements may *possibly* be operative in saving the life of the crab, or *may* be only a correlative of some other life-preserving structure; that its quality in this respect should be inquired into by means of hypothesis and experiment; and that, until this is done, it is *premature* to speak of a particular frontal proportion as having for its *effect* the survival of those crabs distinguished by its possession.

The chief task of the student of living things seems to me to lie in the search for such explanations, even though the task is in some cases to all appearance at first sight hopeless, and even though too hopeful and imaginative spirits may be led, not unfrequently, to propound explanations which are insufficiently supported by observed facts, or are demolished by the observation of other facts. You can not (it seems to me) reduce natural history, as Prof. Weldon proposes, to an unimaginative statistical form, without either ignoring or abandoning its most interesting problems, and at the same time refusing to employ the universal method by which mankind has gained new knowledge of the phenomena of nature—that, namely, of imaginative hypothesis and consequent experiment. I think that most naturalists will agree with Johannes Müller that "Die Phantasie ist ein unentbehrliches Gut." E. RAY LANKESTER.

Dinard, Bretagne, August 10.

Habits and Distribution of Galeodes.

WILL you be good enough to publish in your widely-read paper the following notes on the geographical distribution of *Solfuga* (*Galeodes*) *araneoides*, as the published accounts of that arachnid are incomplete in that respect.

In India it is found in the central parts of India, in the Punjab, in Afghanistan, in Baluchistan. Probably it will be found in Rajputana and Scinde, and perhaps in some parts of the Dekhan. I have never found it in the alluvial plains of Northern India, nor in Bengal. I have just found it in the Eastern Sudan. Probably it exists in most of the deserts of Asia and Africa. The ones I have found all seem to belong to one species. They are of a light straw colour, often with some black above. A black variety is found on the Afghan frontier. The biggest specimen measured 1¾ inches from the tips of the jaws to the end of the abdomen. They feed on soft insects like moths, and live in holes on the ground. They are very rapid in their movements, and are difficult to catch when on the move. The best way to get them is to put a glass over them when they are lying still in a corner. A big match-box often acts as a good trap. They will run inside it of their own accord. They go up walls, posts, trees, in search of insects, and will jump down from a fair height.

The movements of their jaws when feeding presents a unique sight. The head is small, and the bases of the jaws are bulbous and look like a continuation of the head. When eating they move their jaws alternately, and one gets the impression that the head is jointed and that each side moves alternately. In encounters with spiders, scorpions and centipedes, they usually fare badly. Their belly is so soft, that once caught there, they are done for. Still they are very combative.

I have often tried to settle the point as to whether their bite is painful or poisonous. But I never could succeed in making one bite a human being. E. Cretin.

Suakin Force, July 12.

[The genus Galeodes, represented by several species, is known to extend in Africa from Algeria to Egypt, thence southwards into Somaliland; in Europe, from Greece throughout the steppes of South Russia; in Asia, over the whole of Asia Minor, Arabia, Persia, Baluchistan, Afghanistan and Turkestan, and thence into India, where it has been recorded from the following localities: Punjab (Kohat), Rajputana (Bikanir), Gwalior, Delhi, Secunderabad, Guntakul near Bellary, Birhbum, Bengal and Madras.—R. I. Pocock.]

Nest-building Amphipod in the Broads.

It will be remembered that in 1891, *Cordylophora lacustris* was found in great abundance in Heigham Sound. On the 6th inst,, after collecting in that locality and downward to Potter Heigham Bridge, I noticed at the bottom of the bottle a Crustacean, apparently a Podocerid. On floating a piece of reed stem, covered with colonies of the hydrozoon, in a vessel of water, it was evident that the colonies were thickly studded with nests, from which, in some cases, the antennæ were seen protruding. Several specimens of these Amphipods were secured at once; and these the Rev. T. R. R. Stebbing, F.R.S., has kindly identified. They prove to be *Corophium crassicorne*, Bruzelius. A large colony of the Cordylophora has been preserved in formalin, with the nests. On the following day I met with the same Amphipod, in considerable numbers, between Acle Bridge and the Angel Inn. Henry Scherren.

9 Cavendish Road, Harringay. N.

The Effects of a Strong Magnetic Field upon Electric Discharges in Vacuo.

Some interesting experiments upon the subject of this note were described in Nature, July 19. A small addition to those experiments serves to show the connection between the electric conductivity of the tube and the mean free-path-length of the included molecules.

Using the same form of Crookes' tube as employed by Mr. Swinton, but provided with the platinum Maltese cross to intercept the kathode rays, the shadow of the cross is rotated upon its centre through an angle depending upon the strength of the magnetic field. The motions therefore of the molecules are changed from right lines to spiral lines, and thus their free paths are lengthened—a result equivalent to a further exhaustion of the tube The primary effect of the magnetic field, observed by Mr. Swinton, was an increase of conductivity in the tube. The two experiments therefore show that the conductivity in the tube increases with lengthening of the free paths.

By lowering the tube slowly from a few inches above the pole of the electro-magnet down to contact, the shadow of the cross is seen to rotate slowly, and to become smaller as the luminescent cone contracts to the form shown by Mr. Swinton, with the apex on the bulb.

The rotation of the shadow is reversed by reversing the poles of the magnet; and when the current is reversed in the tube, the green fluorescence appears as a spiral band round the walls of the tube—a right-handed or left-handed helix, according to the polarity of the magnet. Walter Sidgreaves.

Stonyhurst College Laboratory.

THE LIVERPOOL MEETING OF THE BRITISH ASSOCIATION.

THE detailed local arrangements are now progressing rapidly. St. George's Hall, where the reception room and offices will be situated, has just been re-painted and decorated by the Corporation at great cost. The old wooden flooring has been removed so as to expose the beautiful tiled pavement, which has not been seen for many years, and which will not be covered up again until after the meeting. The buildings and rooms allotted to the various Sections were mentioned in the former article. The sectional fittings have now been planned out, and will be commenced at once. Separate electric and oxy-hydrogen lanterns will be provided for all the Sections that desire them. A large lecture theatre, holding over six hundred people, at University College, will be available for joint discussions between the Sections.

The details of most of the excursions have now been arranged, and a special "Excursions Guide," in addition to the "Handbook," has been prepared. Amongst the excursions, that to the Isle of Man at the conclusion of the meeting will probably take a foremost place, both on account of its general attractiveness and of its special scientific interest. This excursion will extend over five days—from Thursday, September 24, to Monday, September 28, inclusive; and the party will break up into four Sections: (1) Archæologists, (2) Geologists, (3) Zoologists, and (4) Botanists, to be conducted by competent leaders over those parts of the island which offer special attractions for scientific study. The geology of the island is varied and interesting, especially as regards the dynamic alteration of the older Palæozoic rocks, the volcanic series and the richly fossiliferous limestones of Carboniferous age, and the wide developments of the glacial deposits; the Prehistoric, Scandinavian, and other early remains are celebrated; the marine fauna and flora are abundant, and the presence of the Liverpool Marine Biological Station at Port Erin affords facilities for dredging expeditions and other biological work.

The detailed programme for the four Sections, which follows, has been arranged by a Committee of the Isle of Man Natural History and Antiquarian Society, acting along with representatives appointed by the Liverpool Executive Committee; and a special appendix to the Liverpool "Handbook," containing an account of the geology, antiquities, and natural history of the island, illustrated by a geological map and a chart, has been drawn up by Mr. P. M. C. Kermode, Mr. G. W. Lamplugh, and Prof. Herdman.

Section I.—Archæologists.

Leaders: Arthur J. Evans, P. M. C. Kermode.

Thursday, 24.—Arrive by steamer from Liverpool about 3 p.m. Reception by his Excellency the Right Hon. Lord Henniker, Lieut.-Governor, at Government House. Headquarters at Douglas.

Friday, 25.—Carriages at 9.30 a.m. for Braddan (see ancient crosses and alignments), St. Trinian's, then Tynwald Hill (see mound, cist, Runic cross, &c.). Lunch at Creg Malin Hotel, Peel, at 1 p.m. See Peel Castle, round tower, cathedral, and crosses. Drive to Crosby,

Ellerslie, and Ballingan Chapel. See Glen Darragh Circle, and then back to Douglas.

Saturday, 26.—Train at 9.30 a.m. to Castletown; arrive Castle Rushen 10.30. See Castle collection of antiquities, &c. Train 12.22 for Port Erin. Lunch 1 p.m. Visit Liverpool Marine Biological Station. Walk to Neolithic Circle on Meayll Hill, then to Cregneish (see chasms), then to Port St. Mary (see Oghams and standing stones). Train to Douglas.

Monday, 28.—Train at 9.35 a.m. to Ramsey. Stop at Sulby Glen at 10.42. Climb Cronk Sumark (see ancient fort). Train to Ramsey, arriving at 1.10 p.m. After lunch visit Masonic Rooms (see casts of crosses, flint implements, &c.) Carriages to Laxey (see King Orry's grave). Electric railway to Baldrine (see ancient fort and "cloven stones"), Keeil Killane (lintel graves), then on to Douglas. The four Sections will dine together at the Sefton Hotel, Douglas, on Monday evening.

SECTION II.—GEOLOGISTS.

Leaders: Prof. W. Boyd Dawkins, G. W. Lamplugh.

Thursday, 24.—Reception at Government House, &c., as before. Headquarters at Douglas.

Friday, 25.—Train at 9 30 to Castletown, walk to Castle Rushden, and then on to Stack of Scarlet, and thence to Poyllvaaish (see carboniferous limestones and contemporaneous volcanic series). Meet carriages at Poyllvaaish, lunch at George Hotel, Castletown, and drive to Langness (see base of carboniferous rocks and Skiddaw slates), and then on to railway station at Ballasalla. Train to Douglas.

Saturday, 26.—Electric Railway at 9.30 a.m. to Laxey, and on to Snaefell. (General view of island, and metamorphism of Skiddaw slates). Meet carriages near the Hut, and drive to Tholt-y-Will. Lunch 1 p.m., drive down the Glen, stopping at various points (see crush-conglomerates of Skiddaw rocks, &c.) on the way to Ramsey. Steamer at 6 p.m. back to Douglas.

Monday, 28.—Carriages at 9.30 a.m. for Crosby, Rockmount (see intrusive dykes in Skiddaws), Lhoob-y-Reeast, Peel (see red sandstones, &c.). After lunch see Peel Castle, &c. Drive to Foxdale (see lead mines and granite outcrop), and then on to Douglas. Final dinner with the other Sections.

SECTION III.—ZOOLOGISTS.

Leaders: Prof. W. A. Herdman, I. C. Thompson.

Thursday, 24.—Reception at Government House, &c., as before. Train at 5.10 p.m. for Port Erin.

Friday, 25.—If the weather is suitable, the day will be spent in dredging, &c., from a steamer, probably to the west of the Isle of Man. If dredging is impossible there is shore collecting, tow-netting in the bay, and work in the Biological Station to fall back upon.

Saturday, 26.—Train at 10.40 to Castletown (see Castle Rushen). Return to Port Erin. Lunch at Bellevue Hotel. Take Section I. over Biological Station. Walk with Sections I. and IV. to Neolithic Circle on Meayll Hill. See Cregneish, chasms, &c., and return to Port Erin.

Monday, 28.—If weather is suitable take steamer to Ramsey, dredging on the way along the east side of Island. Lunch at Ramsey, 1 p.m. (If time permits, join Section I. in seeing collection at Masonic Rooms.) Dredge from steamer on way back to Douglas. Final dinner, and stay night at Douglas.

SECTION IV.—BOTANISTS.

Leaders: Prof. F. E. Weiss, Rev. S. A. P. Kermode.

Thursday, 24.—Reception at Government House, &c., as before. See Mr. Okell's garden and collection of Veronicas. Train at 5.10 (with III.) to Port Erin.

Friday, 25.—Carriages 9.30; drive by "Round Table" to Peel over the mountains. Lunch (with I.); see Castle, &c. Carriages to Foxdale, Malew, and back to Port Erin.

Saturday, 26.—Train (or walk, by shore) to Castletown. See Castle Rushen (with I. and III.). Train to Port Erin. Lunch (with I. and III.). Visit Biological Station and Port Erin Shore. Walk with I. and III. to Neolithic Circle on Meayll Hill, on to chasms, and back to Port Erin. There is good shore-collecting at Port Erin, at Port St. Mary, and at various intermediate points.

Monday, 28.—Train to Douglas; carriages to Laxey. Electric railway to Snaefell. Meet carriages near Hut; drive to Tholt-y-Will. Lunch 1 p.m. Drive down Glen and through Curraghs (marsh plants) to Ballamooar, Jurby (gardens, conifers, &c.), back through Curraghs to Ballaugh railway station. Train to Douglas. Final dinner, and stay night at Douglas.

Some changes are taking place in the list of foreign guests. A few of those who had accepted, find themselves unable to be present; but others who were not expected, or were doubtful, are now coming, including some foreign Professors of medicine, surgery, and allied medical subjects—no doubt out of compliment to the President-elect. The local medical men are organising various arrangements in honour of Sir Joseph Lister.

The Local Secretaries hope to secure Dr. Nansen's presence at the meeting. Before he sailed in the *Fram*, Nansen promised a Liverpool shipowner that he would visit him immediately on his return. He has now been reminded of that promise by telegram to Vardö.

It is becoming possible now to forecast to a considerable extent the scientific work which will be brought before this meeting of the Association, and in a further article next week we shall give a sketch of what will probably be the leading features of the various Sections.

W. A. HERDMAN.

COUNTY COUNCILS AND AGRICULTURE.

THE allocation of public money to County Councils under the Local Taxation (Customs and Excise) Act of 1890 has now been in progress for half-a-dozen years. It was understood, though not expressly stipulated, that this money—the proceeds of an additional tax placed upon beer and spirits—should be devoted to the furtherance of technical education, and in the case of most County Councils it is to this object that the money has been applied. With reference to the permanency of the grant, the Duke of Devonshire (then Lord Hartington), addressing a meeting on December 5, 1890, said: "The best way of securing the fund will be to see that it is used for the purpose for which it was originally granted." And on the previous day, in the House of Commons, Mr. Goschen, at that time Chancellor of the Exchequer, said, in reply to a question: "If County Councils set themselves heartily to work to utilise the grants for important educational purposes, it will probably be difficult for any Minister to persuade Parliament to divert them." Excepting in a few cases where some or all of the grant has been applied to the relief of local rates, the County Councils appear to have loyally adhered to the understanding in accordance with which the money was originally directed into the new channel. The particular form of "important educational purposes" to which aid has been extended has necessarily varied somewhat in different localities, but, on account of the universal pursuit of the industry, agriculture perhaps has received more wide-spread recognition than any other art. The result has been the establishment within recent years of new agricultural colleges and schools, or the grafting of an agricultural department upon educational institutions already in existence. To a third group may be assigned

various organisations which were in operation before the days of County Councils, but to which these latter have felt it right to hold out a helping hand. To what extent these different bodies are carrying out the objects for which they were instituted, is a fair subject of inquiry.

In most cases evidence is forthcoming of two main lines of activity, which, though independent of each other, are nevertheless related. These are on the one hand the instruction of students, and on the other the prosecution of investigations which should prove of interest not only to students but to all who are engaged in agricultural pursuits. Under the first head there is not much room for novelty. The model which was set up when, more than fifty years ago, a small group of far-seeing men—the Prince Consort amongst them—unfurled upon the Cotswold Hills the banner of agricultural education, is the one that, consciously or unconsciously, has always been followed. In all attempts that have since been made to formulate a fairly comprehensive scheme of agricultural tuition, the germs of every system will be found in the curriculum of the Royal Agricultural College, Cirencester. Nevertheless, this curriculum, far from being stereotyped or crystallised, is and always has been susceptible of such modifications as are called for by the exigencies of the times, as was exemplified by the manner in which the dairying industry, at the time of its renaissance, received prompt and adequate recognition. Its permanence, indeed, is due to its elasticity. Many hundreds, perhaps thousands, of students are now receiving in agriculture a good type of technical instruction which a score of years ago could be obtained nowhere else in this country than at Cirencester.

It is to that section of their work in which institutions fostered by County Councils are brought more immediately under the notice of the general public that criticism may be usefully directed. Most agricultural colleges and schools, and probably the agricultural departments of all university colleges which possess them, are engaged in pursuits which may or may not deserve to be dignified by the name of research. In the majority of cases, however, the work is nothing else than demonstration, and it usually takes the form of differential manuring experiments upon various crops in the field. Periodically, reports are published embodying the results. These are noticed in our columns, but we are not often able to point to any work that rises above the level of demonstration, of the same type as the example fields and example crops that are conducted under Government auspices in France. In most instances the results can approximately be stated beforehand. If it is necessary to demonstrate in a number of localities the effects of nitrogen according as it is applied to a crop in the form of nitrate of soda or of sulphate of ammonia, or to show the different effects of basic slag, bones, and superphosphate of lime as sources of phosphorus—to cite these as simple illustrations—then, no doubt, these many-duplicated field experiments serve their purpose. Nevertheless, they do not alter the fact that the best experimental farm—the one that is capable of teaching the most useful lessons—is a farmer's own occupation, for in this case the conditions are known to him with, perhaps, a minuteness of detail that cannot be approached in connection with field experiments in which he is hardly likely to take more than a sort of academical interest. What have the County Councils, through the medium of the institutions to whose support they contribute, yet done towards teaching the farmer to read aright the lessons which he may learn all the year round in his own fields, and the capacity to make correct inferences from which would be invaluable to him?

It is noteworthy that, with hardly an exception, the work of these institutions is restricted to crops and cropping. The fascinating problems associated with animal nutrition have mostly failed to attract them. Perhaps these are considered too difficult, possibly they may be thought too costly. In one or two cases the domain of bacteriology has been invaded, particularly in connection with dairying. A good illustration of the general character of the work undertaken is provided in the current report of the Board of Agriculture on the distribution of grants for agricultural education. In the financial year 1894-95 the Board distributed the sum of £7400 amongst seventeen institutions. It is not very obvious why these institutions and none others were selected, but it is a fact that all, or most of them, are also in receipt of County Council grants. It is stated that, in at least twenty counties of England and Wales, "demonstrations by experimental work in field plots are now undertaken," and *résumés* are given of the work recently done at the institutions which have received grants from the Board.

Altogether it would seem that, whilst the institutions under notice are undoubtedly useful as instruments of agricultural education, their value in other directions might be increased were their labour less diffuse. The boast that a given centre has more fields of demonstration scattered over a larger number of counties, and that its officials have travelled a greater aggregate of miles in the discharge of their duties, than in the case of any other centre, may be gratifying to local pride, but it is not a high object to aim at. There may possibly exist an ambition to make a centre a second Rothamsted, but it must be remembered that it is the "continued effort along a given line," associated with "the limited number of lines undertaken, although the work extends over fifty years," that has secured for Rothamsted its unique reputation. The warning has already gone forth officially to the United States agricultural experiment stations, that concentration of energy upon a few specific objects of investigation is preferable to the diffuse expenditure of force which has hitherto characterised many of the stations. There is no coordinated effort amongst our own institutions; each goes its own way, independent of, and practically ignoring, the others—unless, perchance, there be rivalry. A connecting link, possibly a controlling influence, is needed. Youth is on their side, and they have furnished many proofs that they are not lacking in energy. Quality rather than quantity, however, is the goal at which they should aim in the future conduct of their work.

THE ECLIPSE OF THE SUN.

THE bad news which we published last week regarding the almost general failure of the eclipse observations is tempered by the telegrams which have since been received regarding the weather in Novaya Zemlya and in Siberia.

A telegram from Hammerfest reports success at the former station, though details are yet lacking. As this expedition was organised at the last moment, very little has been said about the instruments to be employed. It may be stated, therefore, that Sir G. Baden-Powell took with him Dr. Stone, of the Radcliffe Observatory, who proposed to make spectroscopic observations, and Mr. Shackleton, one of the computers employed at the Solar Physics Observatory, South Kensington, who observed the eclipse of 1893 in Brazil. Mr. Shackleton was provided by Mr. Norman Lockyer with a powerful prismatic camera with two 3-inch prisms of 60°, and careful testings gave great hopes of its performance.

It was, therefore, to be employed chiefly in investigating the special spectrum of the corona found on the photographs of 1893. As a subsidiary instrument, a telescope of four inches aperture and somewhat long focal length was also arranged to photograph the corona. Both instruments were to be fed with light by a Foucault siderostat.

It is hardly necessary to remark that these instruments are capable of furnishing results of the highest value to solar physicists. We therefore note with satisfaction the still later Reuter telegram from Hammerfest, dated August 17:

Sir George Baden-Powell's yacht *Otaria* has arrived here all well with the members of the British Eclipse Expedition. The party made excellent and valuable observations of the eclipse in Novaya Zemlya. The corona and spectrum were clearly visible, and very satisfactory photographs were taken.

The following telegrams from Russia inform us that one of the parties from Pulkowa, including the excellent spectroscopist Belopolsky, has also been successful.

St. Petersburg, August 15.

According to a telegram from Tiumen, in Western Siberia, the solar eclipse was very successfully observed at that place, and one particularly good photograph was taken. Some stars even are visible.

August 16.

A despatch from Khabarovka, which is the residence of the Governor-General of the maritime territory in the extreme east, states that the astronomical observations of the eclipse taken in the village of Orlovski, on the river Amur, were thoroughly successful. The weather was fine during the eclipse. The astronomers, MM. Belopolsky, Vitram, and Orbinsky, have returned to Khabarovka.

August 18.

A telegram from Khabarovka gives further details of the astronomical observations of the solar eclipse taken on the Amur. The sky at the time was overcast, but during totality the corona and several stars of the first magnitude were distinctly visible through the telescope. The darkness was not complete. Six photographs were taken illustrating the different phases of the eclipse.

We referred last week to the partial success on the west coast of Norway. Mr. John Dover has communicated a letter to Tuesday's *Times*, from which we make the following extract:—

It was thought that the best view would be obtained from a village, Brevik, about twenty miles south-east of Bodö. Leaving Bodö on Saturday evening by steamboat, we passed through the "Saltström" at low tide, and waited near to watch the waters rushing into the fiord as the tide rose. We then proceeded to the village of Brevik, where we landed at two o'clock on Sunday morning. A climb of about twenty minutes brought us to a suitable elevation above the fiord of about 250 feet from whence there was an uninterrupted view to the north-east and east for some miles. Only one small cloud was visible, and that in the west; otherwise the sky was quite clear. There was a perfect sunrise at 3.14 on Sunday morning. The partial eclipse began at 4.1 a.m. The total eclipse began at 4.54, and lasted for 92 secs. At Vadsö the totality would have been 105 secs. The partial eclipse ceased at 5.51. At 4° 54′ 45″, the middle of the eclipse, the sun being completely hidden, the corona around it assumed a distinct form. The corona to north-east was about the length of the sun's diameter and very distinct. On the western edge the corona was about two-thirds the length of the sun's diameter, while to the south-east it was about half a diameter. To the north the corona was very slight indeed, being about one-tenth of a diameter. On the south-western edge of the sun appeared a large red spot which was visible until the totality of the eclipse had quite ceased. A Dutch professor near me observed two small spots on the eastern side, but these escaped my notice. I glanced away from my telescope for a moment to see if any stars were visible, and observed Jupiter and Venus. Mercury and Regulus were also seen by others present. The colour of the moon in front of the sun seemed of a dull grey, while the corona around the sun was of a light cream colour. The sky to north and east appeared of a pale orange colour, while to the west it was of light yellow shade. Two photographers—one from Flensborg, Schleswig, the other an amateur from Oxford—were at work, so that I hope a good photograph of the eclipse may be produced. My great regret was that I did not see any one present with thoroughly good scientific instruments.

We shall publish next week a letter received from Mr. Norman Lockyer, containing an account of the preparations he made to observe the eclipse on the Island of Kiö, assisted by the officers and men of H.M.S. *Volage*. Sir Robert Ball contributes to Wednesday's *Times* a long letter on the observing parties and stations at Vadsö and in the neighbourhood, and Dr. Rambaut makes a similar contribution to the *Daily Chronicle* of the same day. We must also mention that the correspondent of the *Daily Telegraph* gives some interesting notes on the characteristics of the shadow.

NOTES.

The current number of the *Comptes rendus* of the Paris Academy of Sciences contains a statement, by M. Berthelot, with reference to the present condition of the scheme to erect a monument to Lavoisier by international subscription. A Committee to take this matter in hand was formed, in 1894, of members of the Institute of France, and representatives of the French Government, of the Municipal Council of Paris, and of various scientific bodies. A special Committee was nominated to obtain subscriptions, and the result of their appeal has now been made known by the publication of a list of subscribers in a fasciculus issued with the *Comptes rendus*. The amount already received is 47,553 francs (nearly £2000), and subscriptions are still coming in. The Emperor of Russia has authorised the opening of a subscription list in Russia, and has headed the list with a sum of two thousand roubles (£313). The French Minister of Public Instruction will give six thousand francs (£240), and the City of Paris £400. Alsace has contributed 2475 francs (nearly £100) to the fund, Germany about £160, England £130, Austria-Hungary £100, Belgium £24, United States £20, Greece £7, Italy £40, Mexico £4, Netherlands £40, Portugal £24, Roumania £14, Servia £40, Norway and Sweden £80, Switzerland £34. The construction of the monument has been entrusted to M. Barrais.

A strong and representative Committee is being formed in connection with the proposal to inaugurate a memorial to commemorate the inception and extension of submarine telegraphy. Amongst many other influential persons who have agreed to act are:—Viscount Peel, Lord Kelvin, Lord Selborne, the Lord Chief Justice, Mr. Joseph Chamberlain, Sir Richard Webster, Lord George Hamilton, Sir Juland Danvers, Sir Samuel Canning, Sir Eyre Shaw, Sir John Robinson, Admiral Sir Henry J. C. D. Hay, Admiral Sir Anthony Hoskins, Mr. Hubert Herkomer, Mr. Herbert de Reuter, Mr. J. C. Lamb, Mr. W. H. Preece, Dr. John Hopkinson (President of the Institution of Electrical Engineers), Dr. Alexander Muirhead, Mr. Alexander Siemens, and Mr. W. S. Silver. An executive will no doubt be formed from the larger Committee, and the *Electrician* makes a suggestion for their consideration. The introduction and extension of telegraphy are almost exactly coincidental with Her Majesty's reign—the magnetic needle telegraph having been patented by Cooke and Wheatstone on June 12, 1837, and the first telegraph line from Paddington to West Drayton being constructed in 1838-9. The suggestion of our contemporary is that the memorial in question should be inaugurated at the time of the celebration of the sixtieth anniversary of the Queen's reign, on or about June 20 next.

The fourth meeting of the International Congress of Hydrology, Climatology, and Geology will be held at Clermont-Ferrand, Puy de Dôme, from September 28 to October 4.

It is announced in *Science* that, if certain conditions are fulfilled by the City of Chicago, the Field Columbian Museum is to receive two million dollars as an endowment fund from Marshall Field, the founder of the Institute.

THE death is announced of Dr. H. E. Beyrich, Professor of Geology and Palæontology, at Berlin.

WE are sorry to see the announcement of the death of Prof. H. A. Newton, of Yale College, whose work in pure mathematics and mathematical astronomy is well known to men of science.

THE list of new Fellows elected by the Reale Accademia dei Lincei of Rome, with their special subjects of study, is as follows:—Ordinary Fellow, Giovanni Briosi (Botany); Corresponding Fellow, Giacinto Morera (Mechanics); Foreign Fellows, Carl Neumann and Hugo Gyldén (Mechanics), Ludwig Boltzmann and Alfred Cornu (Physics).

THE *British Medical Journal* states that the members of the Liverpool Medical Institution have invited Sir Joseph Lister, President-Elect of the British Association, to a banquet to be given in his honour on September 19. The banquet will take place in the Philharmonic Hall, in which the dinner of the British Medical Association was held on the occasion of the meeting in Liverpool in 1882. The Lord Mayor of Liverpool (the Right Hon. the Earl of Derby) will also be the guest of the Institution, and upwards of one hundred of the more distinguished members of the British Association have been invited to be present. The Blue Hungarian Band has been engaged for the evening, and no effort is being spared by the Dinner Committee to make the festival worthy of the guests, the British Association, and the Medical Institution.

AS announced on July 23, the autumn meeting of the Iron and Steel Institute will commence at Bilbao, on Monday, August 31. The detailed programme has now been distributed, from which it appears that the following papers have been offered for reading:—On the Spanish iron industry, by Don Pablo de Alzola; on the estimation of sulphur in iron ores, by R. W. Atkinson and A. J. Atkinson; on the present position of the iron ore industries of Biscay and Santander, by William Gill; on a new water-cooled hot-blast valve, by William Colquhoun; on the manganese ore deposits of Northern Spain, by Jeremiah Head; on the missing carbon in steel, by T. W. Hogg; a note on the presence of fixed nitrogen in steel, by F. W. Harbord and T. Twynam; further notes on the Walrand process, by G. J. Snelus, F.R.S.; on the roasting of iron ores with a view to their magnetic concentration, by Prof. H. Wedding.

WE regret to notice the report that Herr Lilienthal, whose experiments in artificial flight have on several occasions been described in these columns, has been accidentally killed. According to a Central News telegram, he made an experimental journey on August 11, starting from Gömberg, in the province of Brandenburg. He had flown along safely for over two hundred yards, when a gust of wind suddenly caught and carried him upwards, causing him to lose control over his wings, with the result that he fell to the ground, broke his spine, and died soon afterwards. Herr Lilienthal was reported some time ago to have met with a fatal accident, but happily the news then proved to be incorrect. There does not, however, seem to be any grounds for doubting that he has now actually met his death while carrying out one of his intrepid experiments which have been of such assistance in developing the knowledge of the conditions of flight. It is worth remark that Mr. S. E. Peal, in a letter which we published on August 6, prophesied the probability of the occurrence of an accident such as that which has just ended fatally. He said: "Herr Lilienthal is probably on the right trail. I see he desires to turn and meet the breeze; but in this movement, I fancy the upper central aeroplane—so high above the centre of gravity—will turn him over in a strong wind." Unfortunately the suggested accident has happened, and has deprived science of an enthusiastic experimenter in aërial navigation.

A CORRESPONDENT at Johannesburg has sent us a report, from the Johannesburg *Star*, of some amusing speeches recently made in the Volksraad on the subject of rain-making experiments. It would be a pity to let the richness of the utterances of the members of the Raad be the cause of merely local merriment, so we subjoin the report, trusting that sacrilegious meteorologists will give it their consideration. The report is as follows: "The debate on the memorials from Krugersdorp, requesting the Raad to pass an Act to prevent charges of dynamite being fired into the clouds for rain, was continued. Mr. A. D. Wolmarans spoke in favour of his proposal, and denounced the action of certain persons at Johannesburg as invoking the wrath of God. Mr. Birkenstock said there was nothing irreligious or sacrilegious in these experiments; they were purely scientific experiments. When lightning-conductors were first invented, the same objections were raised against their use. This was not a subject for the Raad to deal with, and he moved as an amendment that the Report of the Memorial Committee to decline to interfere be adopted. The Chairman said it was a monstrous thing to shoot into the clouds; it was nothing less than defiance of the Almighty; it should be made a criminal offence. Mr. Labuschagne was of the opinion that the offenders should be imprisoned. After a further discussion it was resolved, by fifteen to ten votes, to instruct the Government to draft a law to prevent such things happening in future, and submit it this session."

THE Committee of the British Association on Zoological Bibliography and Publication desire to draw attention to the following statement:—It is the general opinion of scientific workers, with which the Committee cordially agrees, (1) that each part of a serial publication should have the date of actual publication, as near as may be, printed on the wrapper, and, when possible, on the last sheet sent to press. (2) That authors' separate copies should be issued with the original pagination and plate-numbers clearly indicated on each page and plate, and with a reference to the original place of publication. (3) That authors' separate copies should not be distributed privately before the paper has been published in the regular manner. The Committee, however, observes that these customs are by no means universal, and asks that they shall be more generally put into force. The Committee further asks for co-operation in the following matter. There are certain rules of conduct upon which the best workers are agreed, but which it is impossible to enforce, and to which it is difficult to convert the mass of writers. These are: (4) That it is desirable to express the subject of one's paper in its title, while keeping the title as concise as possible. (5) That new species should be properly diagnosed and figured when possible. (6) That new names should not be proposed in irrelevant foot-notes, or anonymous paragraphs. (7) That references to previous publications should be made fully and correctly, if possible in accordance with one of the recognised sets of rules for quotation, such as that recently adopted by the French Zoological Society. The Committee points out that these and similar matters are wholly within the control of editors (*rédaction*) and publishing committees, and any assistance in putting them into effect will be valued, not merely by the Committee, but, it is believed, by zoologists in general. Any remarks on the above matters may be addressed to Mr. F. A. Bather, Secretary of the Committee, at the Natural History Museum, Cromwell Road, London, S.W.

AN account of experiments, conducted by G. W. and E. G. Peckham, for testing (1) the range of vision and (2) the colour-sense of spiders, published in a late volume of the *Transactions*

of the Wisconsin Academy, is given in the *American Naturalist*. The evidence offered by the authors is based upon a study of twenty species of Attidæ. This study extended over eight successive summers, during which notes were made of many hundreds of observations. The movements and attitudes of the spiders of the group chosen are wonderfully vivid and expressive. The males, in the mating season, throw themselves into one position when they catch sight of a female, and into quite another at the appearance of another male. This power of expression through different attitudes and movements was of great assistance in determining not only its range of sight, but also its power of distinct vision. The results of these experiments are summed up as follows:—"The Attidæ see their prey (which consists of small insects) when it is motionless, at the distance of five inches; they see insects in motion at much greater distances; they see each other distinctly up to at least twelve inches. The observations on blinded spiders, and the numerous instances in which spiders were close together, and yet out of sight of each other, showing that they were unconscious of each other's presence, render any other explanation of their action unsatisfactory. Sight guides them, not smell."

We learn from *Science* that the U.S. Weather Bureau has issued what it calls a "souvenir" map of the St. Louis tornado of May 27. On one side there is a map showing the weather conditions over the United States on the evening of that day, with the tornado districts indicated by red crosses, and with a brief descriptive text beneath. On the reverse side is an explanation of the wind, weather, and temperature signals of the Bureau.

The Pilot Chart of the North Atlantic Ocean for the month of August shows the probable routes followed by eighty-two bottle-papers thrown from vessels and returned to the U.S. Hydrographic Office between December 1, 1895, and June 1, 1896. Some of the individual drifts are very noteworthy, but the general course of the bottles clearly illustrates the two main features of the general surface circulation of the waters of the North Atlantic: (1) a vast but gentle eddy extending from the equator to the parallel of 48° N., and completely enclosing that portion of the ocean lying between the trades and the anti-trades, in which the currents are feeble in force and variable in direction; and (2) the so-called extension of the Gulf Stream, which proceeds north-eastward and skirts the shores of Iceland on the one hand, and Scotland and Norway on the other. The principal meteorological feature during July was the large areas of fog reported. Several westward-bound vessels met the fog near 25° W., and, with the exception of short intervals, did not have clear weather again till reaching the American coast.

Referring to M. Marmier's paper on the action of currents of high frequency on microbic poisons (noticed in Nature for July 30), Dr. d'Arsonval writes to the *Société Française de Physique* pointing out, in the first place, that he has succeeded in attenuating poisons when frozen, and, in the second place, that he has destroyed the virulence of the venom of the cobra snake by means of currents of high frequency at a temperature not exceeding 40°, although, according to MM. Phisalix and Bertrand, this venom does not ordinarily lose its virulence till it has been heated to 150° in sealed tubes. Dr. d'Arsonval has been led to the conclusion that the action is not due to any heating effects, but is rather of an electrolytic nature. It is not here a matter of ordinary electrolysis with liberation of chemical constituents in the neighbourhood of the electrodes, but rather a series of alternating decompositions and recombinations following each other in rapid succession from molecule to molecule without giving rise to any free products.

The goats of Anatolia seem to be remarkable for their susceptibility to a particular form of pneumonia which, although in some respects resembling the pleuro-pneumonia to which calves are addicted, is yet quite distinct in its microbic origin. M. Nicole, formerly assistant at the Pasteur Institute in Paris, and now director of the Imperial Bacteriological Institute in Constantinople, has made a careful study of this disease, in conjunction with one of his assistants, Réfik-Bey. Constantly associated with the disease the authors have found a bacillococcus which, as its name indicates, is polymorphic in appearance, and might by some be regarded as belonging to a group of micro-organisms known under the collective title of the "bacteria of hæmorrhagic septicæmia," of which the fowl-cholera microbe is usually taken as the type. This group owes its origin to a hypothesis of MM. Nocarde and Leclainche, who regard the various organisms associated with hæmorrhagic septicæmia as mere variations from one parent form, the ovoid bacterium. This hypothesis, although attractive, requires further experimental confirmation before it can be unhesitatingly accepted; and M. Nicole considers that he has shown by his investigations that the organism which he has discovered to be the pathological agent in this pneumonia affection of Anatolian goats, is entirely distinct from that associated with the closely-allied pneumonic disease to which calves are subject.

A great deal has been written about the difficulties surrounding the production of diphtheria toxines of efficient strength in a reasonable space of time. Some investigators have stated that an abundant supply of air is essential in the culture flasks, and specially constructed vessels admitting a current of air have been devised; others, again, assert that meat which has almost commenced to putrify is far more effective than fresh meat. M. Nicole, however, now tells us, in a recent number of the *Annales de l'Institut Pasteur*, that he can procure a powerful toxine in the simplest and briefest possible manner by employing the juice of beef only a few hours after it has been killed, with addition of peptone and salt, the whole being brought to the boiling-point, then filtered, rendered strongly alkaline, and heated for ten minutes at 120° C. After being again filtered, it is distributed in any sort of vessel which may be to hand, and sterilised by being subjected for a quarter of an hour to a temperature of 115° C. The diphtheria microbe is introduced, and the cultures are kept for five days at 37° C., when a toxine of high toxic quality is ready for use. This simple process ought to recommend itself to all who have the preparation of diphtheria toxines to superintend, for M. Nicole tells us that the results he has obtained have never failed, but, on the contrary, have been absolutely constant.

A letter from Messrs. P. and F. Sarasin to the Freiherr von Richthofen, announcing their return from an exploration of the south-east arm of Celebes, is published in the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin*. The explorers report the examination of two lakes hitherto almost unknown to Europeans, the Lakes Matanna and Towuti. These lakes lie in an S-shaped depression between two ranges of mountains. Lake Matanna is of great depth, a sounding in the middle giving 480 metres without bottom. Remains of a prehistoric village built on piles, and now submerged, were discovered, many of the bronze and pottery articles found being very similar to those obtained in such villages in Europe. The surface of Lake Matanna is about 400 metres above sea-level, that of Lake Towuti about 350 metres.

Prof. Dr. Karl Futterer contributes to the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin* an extremely interesting paper containing a detailed comparison of the Ural and Caucasus Mountains. Discussing the similar origin of the

two ranges, and the similarity of conditions affecting the Caucasus and the southern Urals, the various progressive stages of erosive action are carefully traced, and the results taken to illustrate a number of important points in the new science of geomorphology, especially in connection with such examples as the Alleghany Mountains, and the extinct range known to geologists as the "Central German Alps," which now forms the Thuringian and Black Forests, and the Harz.

THE Geodynamic Section of the Meteorological Observatory of Constantinople has just completed the publication of its first year's work, and in the last monthly *Bulletin* (for December 1895) the Director, Dr. Agamennone, summarises the results. The area studied is not confined to the Ottoman Empire, but includes all the countries bordering the eastern end of the Mediterranean. Nevertheless, out of 753 shocks recorded in the *Bulletins* (an average of more than two per day), 400 belong to Turkey; while 236 occurred in Greece, and 55 in Bulgaria. Of the Greek earthquakes, more than two-thirds were felt in the island of Zante. From Persia, the Caucasus, and the region beyond the Caspian Sea, the reports are few in number, but this is probably owing to the want of observers. The slight shocks of course greatly predominate, amounting to 519; 225 were strong, or very strong, and nine disastrous. Most of the records are very brief, but more detailed accounts are given of four earthquakes—those of the Caspian Sea on July 9, the Adriatic Sea on August 9, Pergama on November 13–14, and Salonica on December 2. The value of Dr. Agamennone's work will be evident when we compare this ample chronicle with the list of 49 shocks in the Ottoman Empire during the previous year.

THE difficulty of recognising the direction from which a sound proceeds is a well-known obstacle to the full utilisation of acoustic signals at sea. It often happens that a gun signal, or especially a steam whistle, is supposed by one of the watch to be on the port side, while another hears it to starboard. M. E. Hardy, in *La Nature*, describes an apparatus which should prove effective for determining the direction of the sound waves. Two microphones are placed on board at as large a distance apart as possible, say 100 yards. Each of the microphones is connected with a telephone. The observer holds the forward telephone to his right ear, and the stern telephone to his left. Then, when a signal is given by a vessel straight ahead, he will hear it first in his right ear and then in his left, and the interval will be that required by the sound wave to travel from one microphone to the other. In the case supposed, the interval will be about one-third of a second. When the strange vessel is just abeam, the sounds will strike the microphones at the same instant, and the observer will hear them as coincident. When it is just astern, the left ear will be the first to hear the signal. This method, while capable of fixing the angle between the keel of the vessel and the direction of the stranger, does not decide the port-or-starboard question. This might be done by a similar auxiliary apparatus amidships. Another method described by the same author is based upon the interference of sound waves, the sound being received by a tube dividing into two branches whose ends are placed at a distance apart equal to half the length of the sound wave, and are attached to the ends of a bar capable of rotating in a horizontal plane. When this bar points in the direction whence the wave proceeds, and only then, will the sound heard through the tube vanish by interference. But the wave may be proceeding along the bar either forwards or backwards, so that here again we have an ambiguity. But it must be borne in mind that the choice between two exactly opposite directions is comparatively easy. Considering the differences of pitch of the various bells, whistles, and fog-horns in use, we should prefer the first method. But the sound rays rarely proceed in straight lines from the source, and there are many objective difficulties besides the subjective one mentioned.

IN the May number of the *Records* of the Indian N.W. Geological Survey, Dr. W. T. Blanford sums up the results of recent investigations on the ancient geography of Gondwána-land, the great southern continent of which Australia, peninsular India, Southern Africa and South America are the now isolated remnants. He points out how, one by one, each of these great southern land-masses has been found to contain remains of the peculiar Gondwána flora so different from the contemporaneous (Carboniferous and early Mesozoic) floras of the northern hemisphere, and how in each case a peculiar boulder-bed, accompanied by unquestionable evidence of its glacial origin, has been found associated with them. Recent discoveries in South America have completed the chain of resemblance, and show the great extent of the Gondwána continent. At the same time, if the South American boulder-bed be as truly glacial as that of the other areas, any attempt to explain the occurrence of this glaciation within the Tropics by a shifting of the earth's axis must be finally abandoned. It does not necessarily follow that an unbroken continental tract extended at one and the same time from South America through Africa and India to Australia, but the whole region must at least have been mainly land, at a time when the Pacific Ocean was already as important a terrestrial feature as it is now. This continental mass, too, with its peculiar flora, must have been separated from the northern lands, on which the *Lepidodendron* and *Sigillaria* of our coal-measures flourished, by some barrier, probably the Tethyan Ocean of Suess, of which our present Mediterranean and Caribbean seas are the shrunken remnants. Two recently recorded facts of hydrography are mentioned by Dr. Blanford, as throwing an interesting side-light on the difference now existing between the ancient basin of the Pacific and the modern oceans which occupy part of the site of Gondwána-land. The first is the much slower rate at which the Krakatoa wave of 1883 was propagated through the shallower waters of the South Atlantic than through the deep Pacific. The other is the warm temperature of the bottom-waters of the North-west Indian Ocean, which indicates that they (like those of the Mediterranean) are isolated by some barrier from the cold bottom-currents, and such a barrier must run in precisely the direction required for the ancient connection of India and Southern Africa. Thus evidence from all directions converges to indicate the fundamental difference between Atlantic and Pacific Oceans, and in this, bound up as it is with the history of Gondwána-land, it may well be that the key to many a geological puzzle will yet be found.

THE second and concluding part of Mr. C. D. Sherborn's *Index to the Genera and Species of the Foraminifera* (NON—Z) has been published by the Smithsonian Institution. It shows signs of the most scrupulous care in preparation, and should prove a boon to future workers on the Foraminifera.

THE Jubilee of the Chemical Society of London was celebrated in 1891, and it formed the subject of articles in these columns at the time. A record of the proceedings, together with an account of the history and development of the Society, has now been published in a souvenir volume. Translations are given of the addresses sent by foreign societies, and of the speeches made by the foreign delegates. A translation is also given of M. Dumas' Faraday lecture, as well as abstracts of the five other Faraday lectures. The Society boasts of being the first which was formed solely for the study of chemistry, and success has attended it from its foundation. It soon became a centre of the chemical life of this country, and by its publications it has played the chief part in the advancement of chemistry. The volume

just published will make Fellows of the Society proud of their Fellowship, and will arouse a spirit of emulation among chemists in many parts of the world.

STUDENTS of meteorology will be glad to know that three important essays on Australian weather have, by the generosity of the Hon. Ralph Abercromby, been brought together and published in book form. The first essay, on "Moving Anticyclones in the Southern Hemisphere," by Mr. H. C. Russell, F.R.S., was originally read before the Royal Meteorological Society, and published in the Society's *Journal*. The leading fact brought out in this paper is that Australian weather south of lat. 20° S. is the product of a series of rapidly moving anticyclones, which follow one another with remarkable regularity, and are the great controlling force in determining local weather. These anticyclones travel eastward at the average rate of four hundred miles per day, and they do so with such regularity that the prospect is held out of weather predictions being made some weeks in advance, or even for longer periods. The second essay in the volume is the one, by Mr. H. A. Hunt, on "Southerly Bursters," which won the prize offered by the Hon. Ralph Abercromby. This essay was noted in NATURE in January 1895 (vol. li. p. 230). The third essay, which is also by Mr. Hunt, has for its subject "Types of Australian Weather." This discussion throws much new light upon the source of the greater part of Australian rain, and at the same time forms an important contribution to the study of weather in the southern hemisphere generally. The volume containing these essays is published by Mr. F. W. White, Sydney.

THE additions to the Zoological Society's Gardens during the past week include four Malabar Squirrels (*Sciurus maximus*) from Southern India, presented by Mr. W. J. Stillman; two Sclater's Curassows (*Crax sclateri*) from Minas Geraes (Brazil), presented by Mr. E. Sumead; a Temminck's Stint (*Tringa temmincki*), British, presented by Mr. E. C. Sprawson; a Golden Eagle (*Aquila chrysaetus*) from Spain, presented by Mr. F. Leathly Holt; three Common Blue-birds (*Sialia wilsonii*) from North America, presented by Mr. A. T. Binny; two Stone Curlews (*Œdicnemus scolopax*), British, presented by Mr. W. J. Kidman; two Common Blue-birds (*Sialia wilsonii*) from North America, presented by Mr. Percy Cockshut; three Common Adders (*Vipera berus*), British, presented by Mr. A. Old; three Peruvian Snakes (*Tachymenis peruviana*) from Peru, presented by Mr. A. H. Jamrach; a White-browed Amazon (*Chrysotis albifrons*) from Honduras, purchased; a Wapiti Deer (*Cervus canadensis*, ♀), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

LUNAR PHOTOGRAPHS.—Prof. Weinek, whose artistic skill in the enlargement of lunar photographs cannot but be admired, and who has co operated with the staff of the Lick Observatory in reproducing from their negatives the more interesting features of the moon, has recently made a further contribution to the Vienna Academy of fifteen enlargements of certain details on the lunar surface, as seen at the third quarter. Also, Aristarchus and Herodotus have been drawn with the shadows thrown on the western side as a companion picture to an earlier enlargement in which the shadows are thrown to the east. Dr. Weinek now takes the opportunity of calling attention to the fact that, in many instances, his drawings, indicating the existence of minute detail, have been confirmed by Dr. Gaudibert from optical examination of the moon itself. This remark refers to drawings from original negatives taken both at the Lick and Paris Observatories. The differences between the photographic reproductions and Schmidt's map are admitted, and according to the description furnished by Dr. Gaudibert, it is a little difficult to explain some of the omissions from this well-known authority.

DISTRIBUTION OF BINARY-STAR ORBITS.—Miss Everett gives in *Monthly Notices*, June 1896, pp. 462-466, the results of an attempt to discover if the planes of the orbits of binary stars have any relation to the plane of the Milky Way. To do this, the most accurate values of the elements of fifty-five orbits were taken, and from these the galactic longitudes and latitudes of the poles of the orbits were calculated and tabulated. Gould's value of the position of the galactic northern pole was assumed, viz. R.A. 12h. 42m. 4s. (190° 31′), Decl. +27° 16′ (Epoch 1890). This gives the obliquity of the central line of the Galaxy as 62° 7′, and the position of the ascending node is at R.A. = 18h. 42m. (280° 31′), from which the galactic longitudes are reckoned. On examining the tables, it appears that equal surface zones contain nearly similar numbers of orbit poles, and it is concluded that there is no decided tendency on the part of the poles of the orbits to favour any special region of the celestial sphere, and hence that the planes of the orbits cannot be regarded as having any definite relation to the mean plane of the Galaxy.

COMET 1890 VII.—The orbit of this comet, which was first seen by Dr. Spitaler of Vienna, while searching for one recently discovered by M. Zona of Palermo, has been submitted to a thorough examination by the original discoverer, with the result that the period of six and half years has been confirmed. Consequently, its return to perihelion may be looked for next spring, and Dr. Spitaler has prepared ephemerides to facilitate its search. The most favourable time for observation will be next month, when the comet will be in opposition, but the theoretical brilliancy will be only about one-fourth that possessed at the time of discovery in 1890. The considerable southern declination of the comet will render its detection in these latitudes still more difficult. The next return in 1903 will be still more unfavourable, and though 1909 may offer good chances for observation, the error of position will be larger. Dr. Spitaler thinks that the ephemeris he has prepared for this return is trustworthy to about five minutes of R.A. and forty minutes of Declination.

PHOTOGRAPHY OF SOLAR CORONA.—Count de la Baume Pluvinel has recently discussed the conditions necessary for successfully obtaining photographs of the corona (*Bulletin de la Soc. Ast. de France*, July 1896). The difficulty of the problem lies in the varying intensity of the several parts of the corona, the delicate details being lost in long exposures on the inner region, while in short exposures the outer corona is almost absent. During the eclipse of April 1893, the author attempted to determine the best value of the "photographic action" necessary for depicting the coronal structure without allowing the light from the surrounding sky to produce any deteriorating effect. The term "photographic action" is defined as being proportional to the product of the intensity of the image and the duration of exposure, and is accepted as being constant within certain limits. For this purpose he employed a compound camera having nine object-glasses, with apertures varying from 5 mm. to 155 mm., and average focal length of 1·5 metres. The time of exposure for all was 230 secs., and consequently the photographic action had values varying from 0·24 to 250. From the various photographs obtained he concluded that, for that particular climate (Joal) a photographic action of about 4 was best. From other photographs taken in Brazil, he recommends a value of 10 to be used in future eclipses, this value to be diminished or augmented as the sky light is greater or less than that in 1893. The above law of photographic action ceases to hold beyond certain limits; as the intensity of the light decreases, the time of exposure must be enormously increased, and this fact has led the author to suggest a method of photographing the corona without an eclipse. It involves the design of a telescope with such a ratio between aperture and focal length that the sky illumination will be too feeble to affect the plate, while the slightly greater intensity of the corona will allow of its being photographed with a long exposure.

NANSEN'S POLAR EXPEDITION.

DR. NANSEN arrived at Vardö, Norway, on Thursday, August 13, after an absence of three years. A Reuter telegram says that he left the *Fram* with a companion on March 14, 1895, in lat. 84° N., in order to push further north into the Polar Sea than the *Fram* could penetrate. The expedition accomplished its object in traversing the Polar Sea to a point north of the New Siberia islands. The most northerly

point attained was lat. 86° 14', which is nearly 200 miles further north than had previously been reached. No land was sighted north of 82°. Dr. Nansen and his companion then went south to Franz Josef Land, where they passed the winter, subsisting on bears' flesh and whale blubber. Here they fell in with the *Windward*, of the Jackson-Harmsworth expedition, which brought them to Vardö. It is expected that the *Fram* will eventually arrive at Spitbergen.

With most commendable enterprise, the *Daily Chronicle* published on Saturday, August 15, Dr. Nansen's own narrative of his expedition, telegraphed from Vardö. The narrative is in the highest degree interesting, as well as a striking testimony to the hardihood and indomitable spirit of Dr. Nansen and Lieut. Johansen, who for seventeen months, cut off from all means of retreat, travelled over nearly 700 miles and carried on polar explorations. The telegram published in the *Daily Chronicle* is abridged below; and we are glad to express our acknowledgments to that newspaper for the opportunity afforded us of placing before the readers of NATURE the salient points in this account of Dr. Nansen's explorations of polar regions.

The *Fram* left Jugor Strait August 4, 1893. We had to force our way through much ice along the Siberian coast. We discovered an island in the Kara Sea, and a great number of islands along the coast to Cape Cheljuskin. In several places we found evidences of a glacial epoch, during which Northern Siberia must have been covered by inland ice to a great extent.

On September 15 we were off the mouth of Olenek River, but thought it too late to go in there to fetch our dogs, as we would not risk losing a year. We passed the New Siberian Islands on September 18.

On September 22 we made fast to a floe in latitude 78° 50' N., and longitude 133 37' E., and allowed the ship to be closed in by the ice.

As anticipated, we were gradually drifted north and north-westward. The sea was up to ninety fathoms deep south of 19° N., where the depth suddenly increased, and was from 1600 to 1900 fathoms north of that latitude. This will necessarily upset all previous theories based on a shallow Polar Basin. The sea-bottom was remarkably devoid of organic matter. During the whole drift I had good opportunities to take a series of scientific observations—meteorological, magnetic, astronomical, biological soundings, deep-sea temperatures, examinations for salinity of the sea-water, &c. Under the stratum of cold ice-water covering the surface of the Polar Basin, I soon discovered the warmer and more saline water due to the Gulf Stream, with temperatures from 31° to 33°. We saw no land, and no open water, except narrow cracks, in any direction.

As anticipated, our drift north-westward was most rapid during the winter and spring, while northerly winds stopped or drifted us backwards during the summer. On June 18, 1894, we were on 81° 52' N. lat., but drifted then southward only. On October 21 we passed 82°. On Christmas Eve, 1894, latitude 83° N. was reached, and a few days later 83° 24', the farthest north latitude previously reached by man.

As I anticipated that the *Fram* would soon reach her highest latitude to the north of Franz Josef Land, and that she could not easily fail to carry out the programme of the expedition, viz. to cross the unknown Polar Basin, I decided to leave the ship in order to explore the sea north of her route. Lieut. Johansen accompanied me. On March 3 we reached 84° 4' N. Johansen and I left the *Fram* on March 14, 1895, at 83° 59' N. lat., and 102° 27' longitude East of Greenwich. Our purpose was to explore the sea to the north, reach the highest latitude possible, and then go to Spitzbergen *viâ* Franz Josef Land, where we were certain to find a ship.

On March 22 we were on 83° 10' N. lat. The ice now became rougher, and the drift contrary. On April 3 we were at 85° 50' N., constantly hoping to meet with smoother ice. On April 4 we reached 86° 3' N., but the ice became rougher, until on April 7 it got so bad that I considered it unwise to continue our march in a northerly direction. We were then at lat. 86° 14' N.

I then made an excursion on *ski* further northward in order to examine the possibility of further advance, but I could see nothing but ice of the same description, hummock beyond hummock to the horizon, looking like a sea of frozen breakers, the whole time. We had had a low temperature during nearly three weeks: it was in the neighbourhood of 40° below zero. On April 1 it rose to 8° below, but soon sank again to 38°. The minimum in March was 49° and the maximum 24°. In April the minimum was 38° and the maximum 20°.

On April 8 we began our march towards Franz Josef Land. On April 12 our watches ran down, and we were after that date uncertain of our longitude, but hoped that our dead reckoning was fairly correct. We expected daily to find land in sight, but we looked in vain.

On May 31 we were in 82° 21' N.; on June 4 in 82° 18' N.; but on June 15 we had been drifted north-west to 82° 26'. No land was to be seen, although, according to Payer's map, we had expected to meet with Petermann Land at 83° N. These discrepancies became more and more puzzling as time went on.

We did not reach land until August 6, at 81° 38' N. lat. and about 63° E. long. This proved to be entirely ice-capped islands. In our "kayaks" we made our way westward in open water along these islands.

On August 12 we discovered land extending from south-east to north-west. The country became more and more puzzling, as I could find no agreement with Payer's map. I thought we were in a longitude east of Austria Sound; but if this were correct, we were now travelling straight across Wilczek Land and Dove Glacier, without seeing any land near us.

On August 26 we reached a spot in 81° 13' N. and 56° E., where we wintered. The spring came with sunshine and much open water to the south-west, and we hoped to have an easy voyage to Spitzbergen over floe ice and open water. On May 19 we were at last ready to start, and came to open water on May 23, in 81° 5' N., but we were retarded by storms until June 3. A little south of 81° we found land extending westward, and the open water reached west-north-west along its north coast. But we preferred to travel southward over ice through a broad Sound. We came on June 12 to the south side of the islands, and found much open water, trending westward. We sailed and paddled in this direction in order to proceed across to Spitzbergen from the most western cape, but Payer's map is misleading.

We left Franz Josef Land in the *Windward* on August 7, and had a short and very pleasant passage, thanks to the masterly way in which Captain Brown brought his ship through the ice, and thence in the open sea to Vardö.

BACTERIA AND CARBONATED WATERS.

THE new methods of bacteriological research were early called into requisition to determine what hygienic importance from a bacterial point of view could be ascribed to the gaseous aëration of water.

A large number of experiments have from time to time been carried out, and various points of interest have been investigated, but nevertheless considerable divergence of opinion exists as to the precise hygienic value with which the carbonation of water can be credited.

Some authorities state that in such waters the number of bacteria steadily declines, whilst others again have observed as distinct a multiplication of the bacteria present.

The possibility of these two contingencies is, however, quite conceivable without necessarily impugning the accuracy of the results obtained in either case. In the first place it must be remembered that widely different types of water serve for the manufacture of artificial aërated waters, the bacterial contents of which are likewise widely divergent both qualitatively and quantitatively.

Here, then, in the first instance is a source of discrepancy, for the behaviour of bacteria in carbonated waters, as also under other conditions, primarily depends upon the particular varieties of bacteria which have to be dealt with.

It has been shown that whereas some bacteria rapidly disappear in aërated waters, others again are endowed with fabulous powers of multiplication and longevity.

Thus in one instance a sample of carbonated water was found to contain, one hour after its manufacture, 8350 microbes per cubic centimetre; these figures rose, however, after the lapse of 210 days, to the considerable number of 212,400 per c.c.; later on, however, at the end of 428 days, there were only 46 per c.c.

Again, as regards the duration of vitality of ordinary water microbes under these circumstances, we read of as many as 91 being found per c.c. in a sample of water which was considerably more than two years old.

It is obvious, therefore, that as regards the bacterial contents

of a particular sample of aërated water, the results are in the first instance dependent upon the bacterial quality of the original water employed, and the nature of the particular microbes present, whilst it must be acknowledged that a considerable element of chance is introduced into the results, inasmuch as they so greatly depend upon the time at which the examination happens to be made

Thus in the above example, where such enormous multiplication was observed, no one would hesitate, on the strength of such figures, to condemn that water from a bacterial point of view, whilst if its examination had been longer postponed until it yielded only 46 microbes per c.c., as unhesitating a favourable verdict might have been pronounced upon it. As regards the influence of the bacterial purity of the original water upon the finished article, we have frequent evidence of the paucity of bacteria present when the raw water employed has been deprived of all microbial life by boiling or distillation; but even when such precautions are taken in the first instance, we often find that very considerable numbers of bacteria are present in this water after aëration, a fact which is to be ascribed to the bacterial contamination which subsequently obtains in the process of manufacture. Such contamination may be due to various causes; the storage of the water in reservoirs in the factory has been shown in some cases to be responsible for this result, whilst Dr. Abba has recently called attention to the condition of the bottle-syphons used for the distribution of aërated waters as frequently contributing to bring about this condition of things.

These syphons, he states, in his important report on the aërated waters supplied to Turin, are not only left unsterilised after use, but they are neither washed out nor even emptied completely; hence a deposit is always present, which furnishes ample material for the bacterial contamination of the freshly added water. Another factor which controls to a certain extent the bacterial contents of aërated waters is the amount of carbonic anhydride which is present. This point has been well illustrated by Slater, and Dr. Abba has confirmed his results. Thus:

Amount of carbonic anhydride present per litre. (Grammes.)	Bacteria per c.c.
15·08	299
12·10	388
11·74	435
9·07	1207
8·01	1354
6·90	1580
6·03	2032

Whether the above rise in the bacterial contents on the release of the gas present is due to the diminution of the pressure or to the specific action of the gas being modified, it is difficult to say; probably both causes co-operate in bringing about the result. At present we have no authoritative experimental observations to decide this point.

That carbonic anhydride is capable of exercising very specific action in the case of some micro-organisms in the absence of pressure, was shown some years ago by Dr. Percy Frankland in his experiments on the influence of carbonic anhydride and other gases on the development of micro-organisms (*Proc. Roy. Soc.*, 1889). Three microbes were experimented with—Koch's cholera bacillus, Finkler-Prior's bacillus, and the *Bacillus pyocyaneus*, an organism frequently found in green pus.

These bacteria were exposed on gelatine surfaces to the action of the gas in closed vessels, and after a time they were transferred to vessels containing air only.

In the case of Koch's bacillus and Finkler-Prior's bacillus, no growth whatever appeared in the carbonic anhydride vessel, neither did any sign of vitality make its appearance when the bacilli in question were subsequently transferred to the air vessel.

The case was, however, different with the green-pus bacillus, for although no growths appeared in the presence of the gas, on being removed to the air-vessel, growths did manifest themselves, showing that the carbonic anhydride had not succeeded in destroying the bacilli as it had done the two others.

Here, then, we have an example of the specific action of the gas being controlled by the character of the particular microbe to be dealt with. Some authorities ascribe the action of carbonic anhydride simply to the bacteria being deprived of oxygen by its means, but the absence of oxygen can also not be held entirely responsible for the deleterious action of carbonic anhydride; thus, in an atmosphere deprived of oxygen by means of hydrogen, Dr. Percy Frankland found that the growth of Koch's cholera bacillus was not interfered with at all, but we have seen how fatally it was affected in the absence of oxygen by the carbonic anhydride. Here, then, clearly the presence or absence of oxygen would appear to have no voice in the results obtained.

As regards the behaviour of pathogenic bacteria in carbonated waters, the results so far obtained are decidedly more unanimous.

There is no doubt that a very general impression prevails that a barrier of no mean obstructive power is placed between the consumer and zymotic disease, by the substitution of aerated waters for ordinary drinking-water, at any rate during times of epidemics.

This impression is to a certain extent justified by investigation, but can at the same time only be encouraged to a moderate extent, as the following researches will sufficiently show.

When anthrax bacilli are introduced into ordinary seltzer water, they do not live more than from fifteen minutes to one hour; when the spores, however, are similarly treated, they survive upwards of 154 days.

As, however, anthrax in the condition of bacilli devoid of spores is only very exceptionally met with, we cannot derive much comfort from using seltzer water; fortunately, however, so far the communication of anthrax is not associated with drinking-water, and from a hygienic point of view the above results may be regarded as of, perhaps, more theoretical than practical interest.

Our position with reference to cholera germs and water is, however, on quite a different footing, and it is extremely reassuring to learn, on the authority of such investigators as Hochstetter, Slater, and Abba, that in ordinary seltzer and soda water, cholera bacilli cannot live longer than three hours. Dr. Abba records some curious results, in which he states that in *sterilised* tap-water gaseously aerated cholera bacilli persisted as long as forty-eight hours, whilst if such sterilised aerated water is rendered alkaline by the addition of 1 per 1000 bicarbonate of soda, their life was prolonged for as much as twelve days.

It would appear that sterilisation, or the removal of competing water bacteria, materially assisted the life of cholera bacilli; and this impression is confirmed by another experiment with alkalised water, in which the water was not sterilised first, and in which the vitality of the bacilli, instead of reaching twelve, was cut down to seven days.

Unfortunately, as regards typhoid infected water, we cannot resort with any degree of security to carbonated waters, unless we have proof that the manufactured article has been stored for at least a fortnight before use.

Slater observed typhoid bacilli alive in ordinary aërated water as long as eleven days, and both Abba and Hochstetter record a vitality of five days. In some cases, however, they appear to disappear much more rapidly, and doubtless a great deal depends upon the initial vital condition of the particular cultivation of typhoid bacilli employed.

Here again Dr. Abba finds in *sterilised*, alkalised, aerated water, that the persistence of the typhoid bacilli is superior to that observed in similar waters not deprived of their bacterial life.

Dr. Abba has also experimented in a similar manner with the *B. coli communis*, and finds that, beyond its exhibiting the customary character of superior hardiness under adverse circumstances to its near relative, the typhoid bacillus, its behaviour resembled that of the latter. Although storage even for such considerable periods of time as over two years cannot, as we have seen—at any rate in some cases—secure the entire elimination of ordinary water microbes, yet storage of considerably shorter duration is of undoubted service in the destruction of disease germs, as far as our information at present goes.

It would appear reasonable, therefore, to make a practice of storing such waters before distribution, a measure recommended many years ago by Duclaux, and which, in the absence of preliminary precautions, such as the removal of all bacteria present by boiling, distillation or efficient filtration, would appear to be a measure of great hygienic importance.

G. C. FRANKLAND.

A NEW OXYACID OF NITROGEN.

ALTHOUGH rapid strides have been made recently in the chemistry of nitrogen and its inorganic derivatives, since the discovery of hyponitrous acid by Dr. Divers in 1871, no new oxyacid of nitrogen has been described. In the current number of the *Gazzetta Chimica Italiana* (July 31), there is an account by Dr. A. Angeli of the preparation and properties of the sodium and barium salts of a new acid, $H_2N_2O_3$, which fills the gap between hyponitrous and nitrous acids. The method of obtaining this acid is simple and elegant. An alcoholic solution of free hydroxylamine is prepared in the usual manner from hydroxylamine hydrochloride and sodium ethylate, an excess of the latter being taken, and to the solution after filtering off the precipitated salt is cautiously added the theoretical quantity of ethyl nitrate. The reaction proceeds according to the equation $C_2H_5.ONO_2 + NH_2OH = C_2H_5.OH + H_2N_2O_3$, the white sodium salt of the new acid commencing to separate out at once. From this salt, which on analysis proved to be $Na_2N_2O_3$, the barium salt is readily obtained in a pure state by adding barium chloride to the dilute aqueous solution. These salts are both moderately stable in the dry state, but are easily decomposed, on boiling the aqueous solution, into the hydrate of the metal and nitric oxide. The same gas is given off quantitatively on acidifying the aqueous solution, and hence all attempts to isolate the free acid have failed. As regards the composition of this acid, from its mode of formation, the formula $(NO_2)NH.OH$, or nitro-hydroxylamine, naturally follows; and this is to some extent confirmed by the fact that the yellow silver salt, momentarily obtainable from the aqueous solution, is reduced in a few seconds to metallic silver, and Fehling's solution is also readily reduced. The existence of an acid of this composition has already been indicated by Dr. A. Thum, who showed that hydroxylamine salts when oxidised by potassium permanganate in hot alkaline solution take up exactly as much oxygen as corresponds to the formation of $Na_2N_2O_3$, the formula of which might be $O\left\langle\begin{array}{l}N.ONa\\|\\N.ONa\end{array}\right.$. This salt, not yet isolated, is clearly isomeric with the sodium salt above described, since it suffers no further oxidation on boiling with excess of potassium permanganate. It would also yield only one ethyl derivative, whilst nitro-hydroxylamine might be expected to give the isomers $(NO_2).NEt.(OH)$ and $(NO_2).NH.OEt$, which would be readily distinguishable, and this point is being followed up by Dr. Angeli. He has also applied the same reaction to amyl nitrite and to nitrobenzene (*Berichte*, July 27). The amyl nitrite formed a sodium salt, the aqueous solution of which gave a yellow silver salt resembling silver hyponitrite. Nitrobenzene gave a substance which is probably $C_6H_5.NO : N(OH)$, identical with the nitroso-phenylhydroxylamine, $C_6H_5.N(NO).OH$ of Bamberger. The further development of this work, which may be expected to throw light on the constitution of Traube's isonitramine derivatives, Frankland's dinitroethylic acid, and of Pelouze's salt, will be looked for with much interest.

G. N. H.

A RESEARCH ON THE LIQUEFACTION OF HELIUM.[1]

MY experiments on the liquefaction of helium were carried out with a sample of that gas, sent to me by Prof. Ramsay from London, in a sealed glass tube holding about 140 ccm. I take this opportunity of rendering him my most sincere thanks. In his letter Prof Ramsay informed me that the gas had been obtained from the mineral clèvite, and that it was quite free from nitrogen and other impurities, which could be removed by circulation over red-hot magnesium, oxide of copper, soda-lime, and pentoxide of phosphorus. The density of the gas was 2·133 and the ratio of its specific heats (Cp/Cv) 1·652; the latter figure indicating that the molecule of helium was monatomic, as had already been found to be the case with argon.

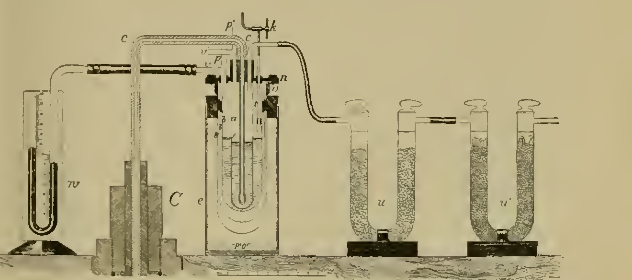
[1] Translated from the original paper, by Prof. K. Olszewski, in the *Bulletin de l'Académie des Sciences de Cracovie* for June 1896, "Ein Versuch, das Helium zu verflünigen," by Morris Travers.

Prof. Ramsay further informed me that the gas was only very slightly soluble in water; 100 ccm. of water dissolving scarcely 0·7 ccm. of helium.

From the results of my earlier experiments I had been led to expect that it would be only possible to liquefy helium at a very low temperature; the small values obtained for the density and solubility of the gas, together with the fact that its molecule is monatomic, indicating a very low boiling-point. For this reason I did not consider it necessary to use liquid ethylene as a preliminary cooling agent, but proceeded directly to conduct my experiments at the lowest temperature that could be produced by means of liquid air. The apparatus employed in these investigations is figured in the accompanying diagram.

The helium was contained in the glass tube, *c*, of the Cailletet's apparatus, C. The tube, *c*, reached to the bottom of a glass vessel, *a*, which was intended to contain the liquid air. The vessel, *a*, was surrounded by three glass cylinders, *b*, *b′*, and *b″*, closed at the bottom and separated from one another. The outer vessel, *b″*, was made just large enough to fit into the brass collar, *o*, which supported the lid, *n*, of the apparatus. The tube, *a*, fitted into an opening in the centre of the lid; the tube, *t*, connected with an apparatus delivering liquid oxygen, passed through a hole on the right. The vessel, *b*, was also connected with a mercury manometer and air-pump by means of a T-tube, *p*, *v*, one arm of which passed through the third hole in the lid of the apparatus. The tube, *a*, was closed by a stopper, through which passed the tube, *c*, of the Cailletet's apparatus, a tube connected with the drying apparatus, *u*, *u′*, and one limb of a T-tube, by means of which the manometer and air-pump could be put in connection with the interior of the vessel. The lower part of the whole apparatus was enclosed in a thick-walled vessel, *e*, containing a layer of phosphorus pentoxide.

By turning the valve, *k*, the vessel, *b*, could be partially filled



with liquid oxygen, which, under a pressure of 10 mm. of mercury, boiled at about −210° C. Almost immediately the gaseous air began to condense and collect in the tube, *a*; a supply of fresh air was constantly maintained through the drying tubes, *u* and *u′*, which were filled with sulphuric acid and soda-lime respectively. When the quantity of liquid air ceased to increase, the tap on the U-tube, *u*, was closed, the T-tube, *p′ v′*, was connected with the manometer and air-pump, and the liquid air was made to boil under a pressure of 10 mm. of mercury. In order to protect the liquid air from its warmer surroundings, a very thin, double wall tube, *f*, reaching to the level of the liquid in the outer vessel, was placed inside the tube *a*. When, as in some of my experiments, liquid oxygen was used in the inner vessel, this part of the apparatus was dispensed with.

Using the apparatus I have just described, I carried out two series of experiments, in which liquid air and liquid oxygen were employed as cooling agents. The tube of the Cailletet's apparatus was thoroughly exhausted by means of a mercury pump, and then carefully filled with dry helium. In the first series of experiments the helium, confined under a pressure of 125 atmospheres, was cooled to the temperature of oxygen boiling, first under atmospheric pressure (−182°·5), and then under a pressure of 10 mm. of mercury (−210°). The helium did not condense under these conditions, and even when, as in subsequent experiments, I expanded the gas till the pressure fell to twenty atmospheres, and in some cases to one atmosphere, I

could not detect the slightest indication that liquefaction had taken place. The first time that I compressed the gas I had, indeed, noticed that a small quantity of a white substance separated out and remained at the bottom of the tube when the pressure was released. Possibly this may have been due to the presence of a small trace of impurity in the helium, but it could not have constituted more than 1 per cent. of the total volume of the gas.

In the second series of experiments I employed liquid air, boiling under a pressure of 10 mm. of mercury. The helium was first confined under a pressure of 140 atmospheres, and then allowed to expand till the pressure fell to twenty atmospheres, or in some cases to one atmosphere. The results of these experiments were also negative, the gas remained perfectly clear during the expansion, and not the slightest trace of liquid could be detected. The boiling point of liquid air was taken, from my previous determination, to be -220° C. (*Comptes rendus*, 1885, p. 238). This number cannot, however, be taken as a constant, as the liquid air, boiling under reduced pressure, becomes gradually poorer in nitrogen. Further, the quantity of nitrogen lost by the liquid air on partial evaporation, varies not only with the rate of boiling, but even according to the manner in which it has been liquefied.

If air, under high pressure, be cooled first to the temperature of boiling ethylene, and then to -150° C., it liquefies, and, on reducing the pressure slowly, liquid air is obtained boiling under atmospheric pressure. During the process a considerable quantity of the liquid air evaporates, and the proportion of nitrogen to oxygen in the remaining liquid is less than in air liquefied under high pressure. If the liquid air, obtained by this process, be made to boil under a pressure of 10 mm. of mercury, the proportion of nitrogen in the mixture continues to decrease, but, on account of the large quantity of oxygen present, the liquid does not solidify, although its temperature is some 6° below the freezing point of nitrogen. When, as in some of my former experiments, the air was liquefied under normal pressure, by means of liquid oxygen boiling under a pressure of 10 mm. of mercury, the ratio of nitrogen to the oxygen in the liquid air was the same as in the gaseous air from which it had been produced. The liquid air, obtained by direct condensation at normal pressure, appeared to lose oxygen and nitrogen with about equal rapidity, and at the end of the experiment a considerable quantity of liquid nitrogen remained behind in the apparatus. On reducing the pressure to 10 mm. of mercury the nitrogen solidified. Prof. Dewar has stated (NATURE, February 6, 1896, p. 329) that liquid air solidifies as such, the solid product containing a slightly smaller percentage of nitrogen than is present in the atmosphere. My experiments have proved this statement to be incorrect; liquid oxygen does not solidify even when boiling under a pressure of 2 mm. of mercury.

After carrying these experiments to a successful conclusion. I found that it was yet necessary to prove that, on reducing the vapour pressure of boiling oxygen to a minimum, no corresponding fall of temperature takes place. The vessel, *c*, was partially filled with liquid oxygen, and, by means of a small syphon, a small quantity of the liquid was allowed to flow into the tube, *a*. The inner vessel, *a*, was then connected with the air-pump and manometer, and the pressure was reduced to 2 mm. of mercury. The oxygen remained liquid and quite clear. In a second experiment the temperature of the liquid oxygen, boiling under 2 mm. of mercury pressure, was measured by means of a thermometer. The temperature indicated lay above -220° C., a temperature easily arrived at by means of liquid air. I therefore concluded that liquid air was a much more efficient cooling agent than liquid oxygen, and that it would be quite unnecessary to make further experiments on the liquefaction of helium.

In every single instance I have obtained negative results, and, as far as my experiments go, helium remains a permanent gas, and apparently much more difficult to liquefy than even hydrogen. The small quantity of the gas at my disposal, and, indeed, the extreme rarity of the minerals from which it is obtained, compelled me to carry out my investigation on a very small scale. Using a larger apparatus, and working at a much higher pressure, I could have submitted the gas to greater expansion. Further, I should have been able to measure the temperature of the gas at the moment of expansion by means of a platinum thermometer, as I did when working with hydrogen; but to make such experiments I should have required 10, if not 100 litres of the gas. As I was unable to determine the temperatures to which I cooled the gas, by any experimental means, I have been obliged to calculate them from Laplace's and Poisson's formula for the change of temperature in a gas during adiabatic expansion.

$$T/T_1 = (p/p_1)^{k-1/k}$$

Where:—

T, p are the initial temperature and pressure of the gas.
T_1, p_1 are the final temperature and pressure of the gas.
k is the ratio (cp/cv) which, for a monatomic gas, is 1·66.

In the first series of experiments the gas, under a pressure of 128 atmospheres, was cooled down to -210° C.

p	T	p_1	T_1	
At.	°	At.	°	°
125	210 C.	50	−229·3 C.	43·7 A.
—	—	20	−242·7 C.	30·3 A.
—	—	10	−250·1 C.	22·9 A.
—	—	5	−255·6 C.	17·4 A.
—		1	−263·9 C.	9·1 A.

The results of these calculations tend to show that the boiling-point of helium lies below -264° C., at least 20° lower than the value I have found for the boiling-point of hydrogen. If the boiling-point of a gas be taken as a simple function of its density, helium, which, according to Prof. Ramsay's determination, has a density 2·133, more than double that of hydrogen, should liquefy at a much higher temperature. Both argon and helium have much lower boiling-points than might be expected, judging from their densities. This anomalous condition may be accounted for by the fact that in each case the molecular structure is monatomic, as shown by the values obtained for the ratios of their specific heats.

The permanent character of helium might be taken advantage of in its application to the gas thermometer. The helium thermometer could be used to advantage in the determination of the critical temperature and boiling-point of hydrogen. To determine whether the hydrogen thermometer is of any value at temperatures below -198° C., I carried out a series of experiments, in which I measured the temperature of liquid oxygen boiling under reduced pressure. I made use of the identical thermometer tube employed by T. Estreicher (*Phil. Mag.* [5] 40, 54, 1898) as a hydrogen thermometer for the same purpose, and applied the same corrections as were made in his experiments.

Pressure.	Temperature.	
	Helium thermometer.	Hydrogen thermometer.*
mm.	°	°
741	−182·6 C.	−182·6 C.
240	−191·8 C.	−191·85 C.
90·4	−198·7 C.	−198·75 C.
12	−209·3 C.	−209·2 C.
9	−210·57 C.	−210·6 C.

The results of these experiments prove that the coefficient of expansion of hydrogen does not change between these limits of temperature, and that the hydrogen thermometer is a perfectly trustworthy instrument even when employed to measure the very lowest temperatures.

I have already pointed out (*Wied. Ann.*, Bd. xxxi. 869, 1887) that the gas thermometer can be used to measure temperatures which lie even below the critical point of the gas with which the instrument is filled. For instance, the critical temperature of hydrogen, which I have found to be $-234·5^\circ$ C. (*Wied. Ann.*, 56, 133; *Phil. Mag.* [5] 40, 202, 1898) can be determined by means of a hydrogen thermometer. The helium thermometer could be used at much lower temperatures, and would probably give a more exact value for the boiling-point of hydrogen than it is possible to obtain by means of a platinum thermometer.

ON PERIODICITY OF GOOD AND BAD SEASONS.[1]

I FEEL some reluctance in coming forward to-night, with the result of my investigations into the periodicity of good and bad seasons—floods and droughts if you will—because they must come to you as a surprise, and they will make a claim on your confidence which at first sight you will probably not be disposed to grant. For myself I know that some years ago, if any one had come to me stating that it was possible to forecast the seasons many years in advance, I should have received the statement with incredulity. The difficulty in getting the facts together is very great. I have had to ask from history records of passing phenomena which it has been the habit of the historian to neglect; however, there will be before you a mass of evidence in support of my proposition, *that there is a periodicity in weather*. The weak point in the evidence is that history has not kept a regular and continuous account of droughts, but only recorded them when they became very prominent. The strong point is that all the data that history does give us is in favour of the nineteen years' cycle.

And it may be explained that the word drought is not used here in the sense in which it is often used in England and elsewhere, that is, to signify a period of a few days or weeks in which not a drop of rain falls; but it is used to signify a period of months or years during which little rain falls, and the country gets burnt up, grass and water disappear, crops become worthless, and sheep and cattle die.

Drought is, however, not wholly made by a deficiency of rainfall. Its most important factors are great heat and drying winds. As an illustration we may look to the year 1895; in the latter part of winter and in spring there were many falls of rain, which would have made grass in ordinary seasons, although there was not as much as usual, but it had no sooner fallen than a dry north-west wind and burning sun dried it all up. This great and burning heat was a well-known feature in historical droughts, and some authorities say that the fable of Phaëton driving the chariot of the Sun so close to the earth that he set it on fire, is a poetical setting of an actual experience in Greece when the sun became so powerful that the heat was almost beyond endurance.

Before 1895 all the diagrams I used had been made to show quantities of the various elements, and their relation in time, with a view to seeing if there was any periodicity. Recently it occurred to me that it would be useful to have a diagram in which all the droughts, without regard to their intensity, should be placed in their order of time; not only was this desirable for seeing what the relation in time was, but it had become evident that it would be impossible to see the relation between our droughts and those in other countries, unless some such pictorial arrangement was made.

As a preliminary to making the diagram, the particulars of the weather in this colony from all sources, for every year of our history, were carefully examined, and the years simply classed as good or bad; that is, having sufficient or insufficient rainfall. A form was then prepared with a vertical space for each year, and across these a zero line was drawn to divide the good from the bad; and, beginning with 1895, I filled in for that year, and below the line, a convenient length of the column in red ink; the length was simply to catch the eye. Then for 1894, a good year, I filled in with black ink, above the line, a space equal to the red in the vertical space for 1894. The two years were thus contrasted simply as good and bad; the question of how good, or how bad, was purposely left out. The diagram was then completed, each year being treated in the same way back to 1788. It was at once apparent that a drought lasting from three to seven years was most regular in its occurrence. A vertical red line was then drawn between the first and second years of each of these dry periods, and it was found that the interval between two successive lines was regular and exactly nineteen years. The centres of another set of dry periods, more intense and relatively shorter than the first series, were found also to recur at intervals of nineteen years. One of these droughts falls regularly between a pair of the more extensive droughts previously referred to.

In the whole period, from the foundation of the colony of New South Wales to the present year, *i.e.* 108 years, it is certainly very noteworthy that the most pronounced droughts recur with great regularity—that is, at every nineteen years throughout the 108 years. Indian droughts seem to have coincided with Australian ones in many instances.

The investigation had become interesting, and seemed to promise to show the exact year of the great drought in this country, of which there was abundant evidence when the colonists landed here, both in the fact that to the south of Sydney all the very large trees were dead, and between them were growing young trees; and the story of the blacks, who said that the river Hunter dried up; that all the great trees died, and most of the blacks; that those who survived had obtained drinking-water from the mountain springs. I had long wanted to find out when this terrible drought in this colony took place, and the Indian record showed that the extensive drought had been repeated in 1769-70, which probably fixes the date; for the middle of the eighteenth century was very dry, generally, all over the world.

But, if we can carry the nineteen years' period in this way back beyond our history, the idea immediately presents itself, where are you going to draw the limit, is there any limit? It was evidently not a question for argument, but for proof or disproof by figures. Tables were prepared showing every date on which droughts of the first class recurred back to A.D. 1, and the same for droughts of the second class. I am not going to weary you by going through the list, but will give you the result. History says very little about droughts prior to A.D. 900. Between that date and this, a drought has, on the assumption, occurred at every nineteen years. In this interval of nine hundred and ninety-six years there have been fifty-two repetitions of drought, and the question is what has history to say about its droughts. Well, it shows that these droughts have been repeated at various places on the earth on forty-four of the fifty-two dates; of these eight missing droughts, no less than six of them occurred between 1000 and 900 A.D., an interval when history was less complete on these matters. So far as I have gone, history furnishes us with seventy-eight droughts in different countries, all of which fit into the first series. During the same period, droughts of the second series recurred fifty-one times, and history records droughts, numbering eighty-nine, on thirty-six of these periods. Taking then the droughts history has recorded between A.D. 900 and 1896, we have seventy-eight of the first series and eighty-nine of the second, a total of one hundred and sixty-seven, out of two hundred and eight on record; but this is not all, for another class of drought, which is irregular in Australia, seems to be more definite and important in the northern hemisphere, and twenty-six more out of the two hundred and eight belong to this series, making up the number to one hundred and ninety-three out of the total of two hundred and eight.

In estimating the importance of these figures, it must be remembered that, before 1788, North and South America, Russia, China, Persia, Turkey, Austria and Australia, all subject to frequent drought, yet did not, however, furnish to the numbers quoted more than you could count on your fingers; and it may be fairly assumed that if we had these records, and especially if history had made a point of recording droughts, we should have had drought recorded on every recurrence of the nineteen years' cycle, of the two chief series; but I think the evidence that history furnishes one hundred and ninety-three recorded droughts, every one of which fits into the cycle, justifies us in assuming that the nineteen years' cycle has been running for at least one thousand years, and may be trusted to continue and justify forecasts based upon it for some time to come.

Having got so much from the study of droughts in the Christian era, it seemed desirable to see if there were any recorded in B.C. times. Records of twenty B.C. droughts were found, all of which, with one exception, fit into our nineteen years' cycle. If these dates are examined apart from their connection with Australian droughts, we find that the intervals between them are multiples of nineteen years, which shows that droughts then, as now, occurred in cycles of nineteen years, which is very strong evidence in favour of our theory, the more so when it is remembered that all the B.C. droughts I have been able to collect, except one, do fit in: they do not form a series of droughts selected for the purpose of supporting it; again, taking the dates given in the various works, the intervals between all these B.C. droughts and those in Australia are multiples of nineteen years.

If it be objected that chronologists have grave doubts about the accuracy of B.C. dates, I reply, that it is quite certain that chronologists did not arrange the dates to make them fit into an

[1] Abridged from a paper read before the Royal Society of New South Wales, June 3, by H. C. Russell, C.M.G., F.R.S.

unknown cycle running amongst these droughts, or in connection with Australian droughts, the dates of which have been unknown until now. These dates are points in history, and the fact that they fall into a cycle of weather, itself supported by all the available drought dates of the last thousand years of history, is in strong confirmation of the accuracy of these B.C. dates.

These intervals in which our droughts are found repeated are surprising, but I am not unaware of the differences of opinion in regard to chronology, but take the dates as given, and it is remarkable how exactly they fit in. But there is another point of importance hidden in these dates, and probably you have not noticed it. Pharaoh's drought was predicted, and a Jew was made chief man under the king, and he was doubtless versed in much of the wisdom of the priests, and carried that wisdom to the Jewish priests, who did not forget it, as the figures make manifest, and if warning of such evils could be depended upon, it is not likely they would forget it. The figures show that Elijah's prediction was a repetition of Pharaoh's drought 42×19 years after it; also Elisha's prediction was nineteen years after Elijah's, and it is noteworthy that the drought in David's time, although it does not appear to have been predicted, was 19×36 after Pharaoh's. This seems to me to be very strong evidence in favour of the view that the Egyptians knew of the nineteen years' cycle, and that the Jews brought the knowledge away with them.

Those learned in Assyrian antiquities tell us that the book containing "the Observations of Bel," the oldest astronomical book of that part of the world, was ordered to be kept by the king 3800 years B.C.; that book shows that they kept a record of astronomical and all other events, that they had discovered the nineteen years' cycle of eclipses, and we are told that it was a doctrine with them, that one event caused another, and all astronomical and meteorological observations were thus bound up together. Under such conditions I do not think it would be possible for them to avoid finding in the droughts a similar period to that in the eclipses, *i.e.* nineteen years; but even if they did, it would have been impossible for those who kept the Nilometer in Egypt to avoid finding it in the heights of the Nile floods, which were of such vital importance and so carefully recorded.

Since I have been working at this subject there have been a number of red rain storms noted in New South Wales, and the latest, on April 10, suggested to me this line of investigation. Red dust is obviously a proof of drought somewhere, otherwise the dust could not rise; and since these proofs of drought are entirely apart from the others, and recorded not as droughts but as marvels, which in days gone by created no little alarm, it will be worth while to see how far they support or contradict the nineteen years' cycle. The result of this resolution came as a surprise to me, because it was so unexpected; I had no idea there were so many records of red rains, or that they went so far back in history.

There are altogether sixty-nine recorded instances of the fall of red rain; of these I have recorded six for New South Wales. The first was fourteen years after the foundation of the city of Rome, that is in B.C. 738, and there are nine others B.C., all of which fit into the nineteen years' cycle; between 538 B.C. to 582 A.D. I can find no record of red rain, but from 582 to 1896 there are fifty-nine recorded falls of red rain, and all of them fit into the nineteen years' cycle. We have here, then, ten B.C. droughts which go with the eight mentioned before to make eighteen B.C. droughts in support of the cycle, the remainder, fifty-nine, are included in the previous list.

I have endeavoured to put before you some of the reasons which have convinced me that there is a cycle in weather; but the necessity for brevity in order to keep within the limits of one address, has rendered it necessary to express in a few sentences the results of many separate investigations, and the evidence does not seem so strong when thus condensed as it does when a number of facts one by one are brought to light from diverse sources, all of which individually support the proposition. I can assure you that the evidence was far more convincing when taken in detail; but want of time to get these details into one address, make this course impossible. Enough appears to have been said to prove that the cycle does exist, and to show the very great importance of this re-discovery of a law of climate which. there are many reasons to think, was well known to the Jews, the Egyptians, and other ancient peoples; they at least knew how to forecast droughts successfully, and in Egypt, like sensible people, made provisions for them.

An examination of the weather of one hundred years of New South Wales has shown that certain features recur every nineteen years; we have seen that the droughts of history—the great and conspicuous droughts I mean—all drop into this same cycle: both those that happened before the birth of Christ, and those that have occurred in our era; for instance, Elijah's drought happened in B.C. 908, that is, 2736 before our great drought in 1828, and the interval is 19×144. Great hurricanes, the great frosts of history, all the red rains, and all the droughts that history records, with a very few exceptions, likewise are included in this cycle, and the level of great lakes in Palestine, South America, and New South Wales are subject to the same mysterious influence that controls our weather.

As my investigation proceeded, the weight of evidence gradually converged upon the moon as the exciting cause. I have never had any sympathy with the theory of lunar influence upon weather, and received, rather against my will, the evidence that presented itself; still the logic of facts left no alternative but to accept the moon as prime motor. There has not been time to complete this investigation, and when finished it must form another paper. Meantime I may say that, so far, the comparison of the moon's positions in relation to the sun and earth and droughts shows that when the eclipses congregate about the equinoxes, that is, in March and September, they do so in the years which give us great droughts. Further, that when the eclipses accumulate in February and March, that is, at the vernal equinox and the month before it, and September, the autumnal equinox, and the month before it, August, we have the more intense and relatively shorter droughts of the second series, with heat, gales and hurricanes; on the other hand, when they accumulate about March and April, that is, the month of equinox, and the one following, and about September, the month of equinox, and October following it, we have droughts of the first series that are less severe, but much longer than the droughts of the second series. I have spoken chiefly of droughts; though, so far as our own history is concerned, it would have served the purpose just as well if I had taken up the periodicity of wet years, but outside Australia it would have been very difficult to get the necessary data, for history has much more to say about the horrors of drought than the abundance of wet seasons.

SNAKE VENOM AND ANTI-VENOMOUS SERUM.[1]

I HAVE already recorded in a series of memoirs published since 1892 in the *Annales de l'Institut Pasteur* and in the *Comptes rendus de l'Académie des Sciences*, the results of my researches on the venom of snakes, on the immunisation of animals against this venom, and upon the production of an anti-venomous serum. Prof. Fraser has confirmed the facts that I have published, and has successfully repeated almost all my experiments. I bring before you, to-day, a series of new facts relative to the same question. I may say at the outset, in contradiction of the opinion recently expressed by certain physiologists, that it is fully proved that the venoms of the various species of snakes produce physiological phenomena which have certain features common to all, and that the actions of these venoms only differ as regards their local effects. It is now possible to separate, artificially, the substances which produce the local phenomena from those which produce the bulbar intoxication. This separation may be effected by means of heat. If any sample of venom be thrown into watery solution and heated at 85° C. for a period of fifteen minutes, the albumin contained in the solution is coagulated and the phlogogenic substances are destroyed, whilst the toxicity of the substance is entirely unaffected. MM. Phisalix and Bertrand have already demonstrated this fact in the case of the venom of the viper found in France. After heating at 85° C. and filtration, all venoms, both viperine and colubrine, produce the same effects; they only differ as to the degree of their toxic activities. Similarly all are destroyed by the hypochlorites of the alkalis and by chloride of gold, the use of which substances I have suggested—particularly the hypochlorite of lime in a solution of

[1] Abridged from a paper read before the Section of Pathology and Bacteriology of the British Medical Association, by Prof. A. Calmette, Director of the Pasteur Institute, Lille.

1 in 60—for the local treatment of snake bites, to prevent the absorption of the venom.

Quite recently M. Phisalix, assistant in the Paris Museum, has announced that he has succeeded in separating the vaccinating substance of venom by filtering it through a Chamberland filter. The animals into which this experimenter inoculated the filtered venom did not die, and he found that they were vaccinated against the inoculation of a lethal dose of non-filtered venom. I have repeated these experiments with the greatest care, but the results that I have obtained are very different from those obtained by M. Phisalix. When a solution of normal venom is filtered through a Chamberland bougie a great part of the venom is kept back by the porcelain, just as is the case when microbic toxines are similarly filtered. It is certainly found necessary to use two and a half times more of the filtered venom than of the non-filtered venom in order to kill animals of the same weight; but if before filtration care is taken to separate the albumin of the venom by heat, it is found that the porcelain no longer keeps back any of the toxic substance. The animals are killed by the same dose of solution both before and after filtration. It follows very evidently, therefore, if the venom which has not been freed from albumin is less toxic after filtration than before, that this must be due to the fact that the albumin adheres to the porous wall of the filter, so forming a perfect dialysing membrane through which the venom can pass only with very great difficulty. I have been able to prove this by restoring a certain proportion of albumin by means of the addition of normal serum to venom that had previously been deprived of its albumin by heat. On filtering this venom containing the added albumin, I found that the liquid which passed through the filter was again considerably less toxic. Animals which have received filtered venom, and which have not succumbed after the lapse of three days, resist a minimal lethal dose of venom—*i.e.* they do not die; they are already vaccinated, just as are those that have been injected with a less than lethal dose of normal venom. There is, I believe, no reason to suppose that, as has been maintained by Phisalix and Bertrand, there is brought about by heat or by filtration of venom any separation of two substances, the one toxic and the other vaccinating, which are supposed to be found together in normal venom. This hypothesis does not appear to me to be justified by experiment, and it is absolutely certain that if one inoculates an animal with a quantity of heated venom, or of filtered venom of which the toxicity has been modified in sufficient quantity to kill the animal, it will react exactly as if it had been injected with a dose of normal venom a little below that required to produce death. In both cases, and in the same time, the animal acquires through this inoculation a state of resistance which enables it, at the end of several days, to receive with impunity an amount of venom capable of killing animals of the same weight. The serum of animals vaccinated against one species of very active venom, such as the venom of the cobra for example, is perfectly antitoxic as regards the venom of all other species of snakes, and also, as I have been able to prove, against the venom of scorpions.

The best method of procedure for the purpose of vaccinating large animals destined to produce anti-venomous serum consists in injecting them from the outset with gradually increasing quantities of the venom of the cobra mixed with diminishing quantities of a 1 in 60 solution of hypochlorite of lime. The condition and the variations in the weights of the animals are carefully followed in order that the injections may be made less frequently if the animals do not thrive well. Quantities of stronger and stronger venom are in turn injected, first considerably diluted and then more concentrated, and in order that the animals (horses) may give a serum equally active for the various phlogogenic substances which determine the various local actions it is necessary, when they have already acquired a sufficiently perfect immunity, to inject the venoms derived from as large a number of different species of snakes as possible. The duration of the treatment is of considerable length, at least fifteen months, before the serum is sufficiently active to be used for the purposes of treatment. The serum that we actually prepare at the Institut Pasteur, Lille, is active to the degree of 1 200,000th, that is to say, it suffices to inject, as a prophylactic dose, into a rabbit a quantity of serum equal to the 200,000th part of its weight in order to protect it against a dose of venom killing an animal of equal weight in three or four hours. If this serum be injected after the venom, it is sufficiently active in a dose of ½ c.c. given thirty-three minutes after the inoculation of a dose of venom lethal in three or four hours to prevent the death of the animal. Large quantities of this serum have been sent during the last few months to India, to Cochin China, to Australia, and to other countries where venomous serpents are most frequently met with, and we have already been able to collect certain interesting observations on people bitten. It is, however, very difficult in the greater number of instances to obtain information as to the species of venomous snake that has inflicted the wound. It has seldom been found possible to kill or capture on the field the snake inflicting the bite, so that all the statements as to the species of the snake which have not been so determined must be considered as open to some suspicion. I have already published one case, a most conclusive one, that of an Annamite bitten very severely in the hand by a cobra at the Bacteriological Laboratory of Saigon, who was cured by a single injection of 10 c.c. of serum. I have quite recently received the report of another very interesting case, for which I am indebted to Mr. Hankin, director of the laboratory of Agra in India. The patient in this instance was bitten by one of the most dangerous reptiles found in India, the Bungarus.

It has, indeed, been fully demonstrated, both by experiments on animals and by the actual treatment of snake bites in the human subject, that we have in anti-venomous serum a "specific" remedy which is very efficacious against venomous bites. It is, therefore, surely necessary to hasten to distribute it in all those countries where dangerous snakes are found. The only real difficulty consists in procuring sufficient quantities of venom for the immunisation of large animals, such as horses, to furnish adequate quantities of serum. The Pasteur Institute at Lille actually possesses enough venom, and horses completely immunised numerous enough for the most pressing wants. Serum prepared in an absolutely pure condition can be preserved for more than a year without losing any of its curative properties. In all countries where snakes claim their numerous victims, and especially in India, where the annual number of deaths resulting from venomous bites rises to about 22,000, it would surely be expedient that the various Governments should take steps to establish depôts, at least, in the principal agricultural, forest, and mining districts, where medical aid may be afforded as early as possible to every person bitten who comes to seek treatment. Each of these posts should be supplied with (1) a stock of serum, renewed each year; (2) hypodermic injection syringes; (3) a perfectly freshly prepared solution of hypochlorite of lime, and other medicaments and instruments necessary for the dressing of wounds. The expense of effecting such an organisation would be very slight. I ask you, gentlemen, to pass unanimously a resolution that may have the effect of inducing, or affording justification to, the Indian Government to realise this humanitarian scheme.

Dr. Calmette delivered a lecture, with experimental illustrations, in the Laboratories of the Conjoint Board of the Royal College of Physicians and Surgeons, on "The Treatment of Animals poisoned with Snake Venom by the injection of Anti-Venomous Serum." In the course of his lecture he said:

I have to-day the opportunity of giving you the results of experiments that have been performed under Dr. Woodhead's licence, but under my direct personal supervision, so that they may be depended upon as affording direct proof of the value of my method. Those animals that have been successfully treated you may examine for yourselves; others that have been poisoned with the snake venom, but have not received the serum, have succumbed; these latter serve as control experiments with which to compare the results obtained when the serum has been given.

These experiments are easily carried out, and are absolutely painless. In rabbits, as in the human subject, the first symptom indicating the action of snake poison is slight somnolence, which, becoming more and more marked, is gradually succeeded by a condition of unconsciousness associated with, first, muscular contraction and then with loss of motor power, which, commencing in the hind limbs, passes forwards until the respiratory centres are affected, the cardiac centre being the last attacked. When the animal dies, the heart is found in a condition of diastole. The venom may be injected in two ways—intravenously, when a comparatively small dose acts with great rapidity; and subcutaneously, when the dose also acts powerfully but more slowly. A lethal dose of cobra poison injected

subcutaneously is about 1 milligramme of dried substance, which proves lethal in about twelve hours. Twice this quantity injected into the veins kills a rabbit of about 1500 grammes in sixteen minutes. Five times as much introduced subcutaneously proves fatal in about three and a half hours. I may, however, give you the results of experiments devised to bring out the exact action of the anti-venomous serum, which experiments have been followed by those who are working in these laboratories.

To exhibit the efficiency of protective injections, at nine o'clock this morning four rabbits, weighing between 1450 and 1770 grammes, were injected intravenously in the lateral aural vein, each with 3 c.c. of the anti-venomous serum. This afternoon these rabbits have been injected intravenously with 2 milligrammes of dissolved dried venom sufficient to kill the animal in sixteen or seventeen minutes. None of these animals show any symptom of sleepiness, and it is evident that the venom will have little, if any, effect upon them. At the time that these animals were injected with the two lethal doses, two control rabbits, weighing 1340 and 1275 grammes respectively, were similarly injected intravenously with 2 milligrammes of the venom; these both succumbed to the symptoms above-mentioned, one in about sixteen minutes and the other in seventeen minutes. We have here, then, ample evidence of the great protective power that the serum exerts when injected into the body before the venom is introduced. In a second series of experiments, carried out to demonstrate the curative properties of this serum, six rabbits were similarly treated with 5 milligrammes of venom injected under the skin. Half an hour afterwards two of these animals received 3 c.c. of the serum intravenously; neither of them showed any symptoms of poisoning, and remained perfectly well. Two others of these poisoned animals, one hour after the venom had been introduced, were similarly injected intravenously with 3 c.c. of the serum; they also remained well. Two of the other rabbits should have been left for one and a half hours, but the dose of poison was so large that one of the animals succumbed at the end of an hour and twenty minutes; the other animal was immediately injected with the same dose of serum as above, with the result that it is now well, although the dose of venom was so large and had been allowed to act for so long a time—long enough, indeed, to kill the other animal injected at the same time. This is a very striking proof of the efficacy of the serum.

Although the anti-venomous serum does not act directly upon the toxin, but only through the cells, it begins to exert its influence immediately it is introduced into the body. This fact is well brought out by the following experiments:—Three c.c. of the serum were injected into the lateral vein of the left ear of a rabbit weighing 1280 grammes; fifteen minutes later this animal received into the lateral vein of the right ear 2 milligrammes of the venom, sufficient to kill it in less than twenty minutes had it not received the serum. The animal has remained perfectly well, and still shows no evidence of poisoning by snake venom. A more striking experiment still is one of which I give a description. A rabbit having received intravenously 2 milligrammes of venom, two minutes later is injected with 5 c.c. of the anti-venomous serum in the vein of the opposite ear. The animal has remained perfectly well.[1] Such an experiment shows that the venom does not destroy the cellular elements at once, and that even when the poison has already found its way to the circulation these cells may be rendered insensible to the action of the poison by means of the action of the serum.

[Dr. Calmette then gave extracts from the paper which he brought before the British Medical Association at Carlisle, and concluded by asking Dr. Woodhead to read the following.]

Gentlemen, the experiments that have been described to you concerning the efficacy of the "anti-venomous serum," the results of which you have before you, prove that the said serum really constitutes a specific remedy against venomous snake-bites. The use of this serum must necessarily become generalised at no distant date in all countries where venomous snakes are found, in order that both men and domestic animals may be protected. Is it not advisable, therefore, for the British or Colonial Governments, which are deeply interested in this matter, to take rigorous measures to prevent the sale in England and in its colonies of serums for which no absolute guarantee of efficacy and purity is given? I have the honour to propose that you will adopt the following propositions, and bring them in some way before the Government at as early a date as possible:—

(1) That there be instituted in London and in each British colony where there are found venomous snakes a sanitary committee, to be entrusted with the duty of testing the efficacy of anti-venomous serums offered for sale or sent out to be delivered gratuitously by druggists and others.

(2) That no bottle shall be sold or distributed unless bearing the mark of such control.

(3) That this control be effected according to the sole, simple, and rapid method which alone presents every guarantee of accuracy.

(4) The method proposed is the following:—A standard solution of venom will be placed at the disposal of the appointed experts. The toxic unit of this solution will be based on the quantity of venom necessary to kill a rabbit of 2 kilogrammes in twenty minutes by intravenous inoculation in the marginal vein of the ear, the above quantity corresponding on an average to 2 milligrammes of cobra venom (weighed dry) and to 4 milligrammes of rattlesnake venom. An anti-venomous serum, to be sufficiently active for therapeutic use, must be a preservative in a minimum dose of 2 c.c. on intravenous injection into a rabbit of 2 kilogrammes against an intravenous injection of the toxic unit of venom. The preventive inoculation must be made fifteen minutes only before the inoculation of the venom. The testing of the serum is thus effected in less than one half-hour.

(5) That stations provided with serum and all the necessary apparatus for its application be established in the principal centres of agriculture and in the mining and forest districts of the colonies infested with venomous snakes, such as Australia, Burmah, and India, so that every person bitten may be able to come at once and receive treatment.

[1] All these animals were still alive and in excellent health eight days later.

REPORT OF THE DEPARTMENT OF SCIENCE AND ART.

THE forty-third Report of the Department of Science and Art, dealing with the work of the Department during the past year, has just been issued in the form of a Blue-book. The report may be taken as a statement of the condition of elementary science teaching in this country; therefore, some of the facts and opinions contained in it are worth recording.

In the science division it is pointed out that in the decennial period, from 1886 to 1895, the number of schools has increased from 1682 to 2673, of classes from 5862 to 9545, and of students from 94,838 to 193,404. Of the 193,404 pupils under instruction in 1895, 188,380 come within the category of those on account of whose instruction payments on the results of examinations are made by the Department. Of the schools examined, 2139 were in England and Wales, 366 in Scotland, and 168 in Ireland. There were 113,398 individual students examined, and 52,079 were successful in passing in one or more subjects. The payments to Science Schools, exclusive of those made to Training Colleges on the results of the examinations for the year 1895, amounted to £142,543, an increase of more than £2000 on the preceding year.

Of the 2673 Departmental Science Schools in 1895, 115 were Organised Science Schools, that is to say, schools in which organised courses of instruction are followed. A new scheme of work for such schools came into force last year, and so far it appears to have worked satisfactorily. Practical physics was made obligatory in these schools by the new scheme, and the result is that while only a few years ago a physical laboratory was a rarity, one will shortly be found in every school in which science forms a proper place in the curriculum.

Mr. C. A. Buckmaster, one of the senior inspectors, places his finger upon a weak point in the education of teachers when he says, "the great failing of the elementary teacher as a science instructor is not want of knowledge, but want of ability to experiment." The reason is that few Training Colleges provide facilities for courses of experimental work, though such scientific practice should be an essential condition for the teaching of science subjects in the Elementary School Code.

Throughout the reports of the inspectors the welcome information is made known that experimental work in science is becoming more common, but there is still much room for improvement. The supply of apparatus is being largely increased, and laboratory accommodation is being extended. The chief difficulty to be contended with at the present time is the insufficient education of the students who join the evening classes. Especially is there a lack of knowledge of scientific principles, and there is a difficulty in getting students to take up subjects which lie at the bottom of all technical subjects. On this point Dr. H. H. Hoffert says: "It is much to be desired that as Technical Institutes multiply, and permanent staffs of well-qualified teachers become appointed, more encouragement may be given to students of evening classes to take up definite courses of study. Such students too frequently attempt the study of the more purely technical and applied subjects, without having the necessary knowledge of the underlying sciences, and in consequence of this the teaching is largely based on rule-of-thumb methods of practice, and is lacking in scientific generality and educational value. There is an undue disproportion in number between classes on such subjects as applied mechanics, steam, and mining, and those in theoretical mechanics, elementary physics, chemistry and geology."

In addition to the reports on instruction in science and art, the Blue-book just issued contains as appendices reports on the Royal College of Science, the South Kensington Museum, and other museums in connection with the Department of Science and Art, supported by the State. There is also in it the Report of the Director-General of the Geological Survey of the United Kingdom and the Museum of Practical Geology, and a Report to the Solar Physics Committee on the work done in the Solar Physics Observatory at South Kensington.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE appointments, recently advertised, at the Northampton Institute, Clerkenwell, have been filled as follows:—Mr. John Ashford, Lecturer on Engineering at the Birmingham Technical Schools, to be Head of the Mechanical Engineering and Metal Trades Department; Mr. John Williams to be Head of the Artistic Crafts Department; Mr. C. V. Drysdale to be Chief Assistant in the Applied Physics Department; and Miss Mary A. H. Gibbs to be Head Teacher in the Domestic Economy School.

THE Technical Education Board of the London County Council has addressed a letter to the Councils of University and King's Colleges on the subject of the financial assistance to these institutions during the forthcoming session. It is pointed out in this letter that the Board cannot undertake to ensure regular annual grants towards either of these colleges. It is further recommended that the Councils of the two colleges should confer together before making any application for assistance, with a view to coordinating the work now specially carried on in connection with Oriental languages. A question has been raised with regard to King's College, as to whether the Board can legally make a grant to an institution of a denominational character. But since the discussion of these questions will take some time, it is proposed to continue the grants of £1500 to University College and £1000 to King's College for next year, on the understanding that such a conference shall be held.

THE following complaint, which has been made by *The Local Government Journal*, is not, we think, borne out by the reports of the technical education committees of those County Councils which administer the affairs of the agricultural counties, and which have been sent to us from time to time. The paragraph runs thus: "If technical education committees would bestir themselves and give lessons in thatching, hedging, ditching, sheep-shearing, and so on to the men, instead of providing an afternoon's amusement for labourers' wives in showing them how to make butter without having a cow to produce the milk, and similar instruction for farmers' wives and daughters when the ladies of the farm have no intention of making butter, or of bending their backs to skim the milk, much more good would be done than is accomplished at present, and a great waste of treasure would be obviated." More than one committee in charge of technical instruction would be grateful to our contemporary for some successful method of getting farm-labourers together for the purpose of agricultural instruction, though we have our opinion of the wisdom of teaching the subjects named, even if these arts are not included in the well-known restriction of the Technical Instruction Act.

SCIENTIFIC SERIALS.

American Journal of Science, August.—Molluscan archetype considered as a *veliger*-like form, by A. E. Verrill. In the form of molluscan larva known as *veliger*, and in its slightly younger stages, we have organisms that swim free, often seek their own food, and seem to have claims to be considered the nearest living representatives of the ancestral molluscan archetype, or archetypes, for it is quite probable that the different classes of Mollusca have descended from distinctly differentiated *veliger*-like organisms. In general, it may be stated that nearly all Gastropoda, except certain terrestrial and fresh-water forms, pass through *veliger* stages. The same may be said of Bivalvia, Scaphopoda, and Pteropoda. Cephalopoda, on the other hand, seem to have an abbreviated development, like terrestrial Gastropoda, and leave the egg with the general structure of the adult. It is probable that each of these great classes were originally small, free-swimming forms, furnished with a ciliated locomotive organ similar to the velum of modern veligers. The primitive Cephalopoda had probably a similar origin from a *proveliger* like that of some pteropods and gastropods. On the other hand, it seems impossible to derive a cephalopod or a bivalve from a creeping chiton-like archetype such as Lankester has proposed.—An apparatus for the rapid determination of the surface tensions of liquids, by C. E. Linebarger. The apparatus is based upon Jäger's method of employing two capillary tubes of different bore immersed in the liquid, and measuring the difference of the depths to which they were plunged when air bubbles forced out of them at the bottom required the same air pressure. The tubes employed had bores ranging from 0·1 to 1·5 mm. Two tubes were mounted in clamps in a stand over a test tube containing the liquid, and immersed in a water or glycerine bath. Air pressure was applied, and the orifices were shifted until the liquid was pushed down to the orifices, and there the heights were carefully adjusted until equal streams of bubbles issued from both orifices. The surface tensions were found by the formula

$$\gamma = chs + s^2$$

when γ is the surface tension in dynes per cm., c the apparatus constant, h the distance between the ends of the tubes, and s the specific gravity.—Wardite, a new hydrous basic phosphate of alumina, by J. M. Davison. Mr. Packard's "variscite" from Utah occasionally leaves on decomposition some cavities in the nodules, and encrusting these cavities is a hydrous basic phosphate of alumina, which appears to be a new mineral. It is a light green or bluish green, with vitreous lustre, concretionary structure, hardness about 5, and density 2·77. Its formula is $Al_2(OH)_3PO_4$, and it forms a series with Peganite and Turquois.—On the existence of selenium monoxide, by A. W. Peirce. The author has been unable to find evidence of the existence of the monoxide, either gaseous or solid, and his experiments go to show that the peculiar smell of decayed cabbage, attributed by Berzelius to the monoxide, is only developed when selenium is heated in presence of moisture, if only a mere trace, and is probably due to selenium hydride.

Bulletin of the American Mathematical Society, vol. ii. No. 9, June.—The motions of the atmosphere, and especially its waves, is a translation, by Prof. Cleveland Abbe, of an address by Dr. E. Hermann, which was delivered before the Meteorological Section of the Association of German Naturalists at the annual meeting held in Vienna, September 25, 1894. The author states that the inadvisability of the views according to which the motions of the atmosphere consist in the development of independent cyclones and anticyclones is, of late years, more and more plainly recognised. This conclusion has been arrived at, not so much through a severe criticism of the fundamental basis upon which these erroneous views had been established, as by the power of the facts that resisted introduction into this artificial system. He traces this change of view

to the influence of a memoir by Hann, published some ten years since, and then points out that the idea was further developed in von Helmholtz's "Mechanics of the Earth's Atmosphere." He then expounds his own method, and closes with the hope that it may lead meteorology out of the region of vacillating ideas that now control it into a broader field, and "place it among the exact sciences, where everything is reduced to numerical computation, and thus, to an important extent, further its application to daily practice."—Prof. Osgood writes on some points in the elements of the theory of functions.—On the motion of a homogeneous sphere or spherical shell on an inclined plane, taking into account the rotation of the earth, by Prof. A. S. Chessin, discusses some interesting illustrations akin to Foucault's experiments with the pendulum and the gyroscope.—From the Notes we learn that the Council have arranged for a colloquium in connection with their summer meeting at Buffalo, at which are to be delivered two courses of six lectures each, viz. on the subject of linear differential equations and their application, by Prof. M. Bôcher, and on the Galois theory of equations, by Prof. J. Pierpont.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 10.—M. A. Cornu in the chair.—Researches on cyanic acid, by M. Berthelot. By studying the reaction between acetic acid and potassium cyanate it was found to be possible to separate the heat evolved by the simple replacement of the cyanic by acetic acid, from the heat evolved in the subsequent decomposition into ammonia and carbon dioxide. The value thus found for the heat of neutralisation of cyanic acid (12·25 calories) was confirmed by the observation that no reaction takes place between potassium cyanate and boric acid (heat of neutralisation, 11·6 calories).—Researches on the volatility of lævulic acid, by MM. Berthelot and André. Lævulic acid is slightly volatile *in vacuo* at ordinary temperatures. Analysis of the residual acid showed that its composition was not quite the same as the original acid, possibly owing to the formation of an anhydride.—On the reactions taking place in the cold between phosphoric acid and ether in the presence of water, by MM. Berthelot and André.—M. Marcellin Langlois presented two memoirs on thermochemistry.—On the lunar photographs offered to the Academy by M. Weinek, Director of the Prague Observatory, by M. Lœwy.—On the part played by the dielectric in the discharge by the Röntgen rays, by M. Jean Perrin.—Photography in the interior of a Crookes' tube, by M. G. de Metz. By the use of the method previously described, it has been found possible to draw up tables of relative permeabilities to X-rays and kathode rays. With the exception of lead, which is slightly more transparent for the kathode rays than for the X-rays, the two tables are identical, and even this exception appears to be capable of explanation. The kathode rays, like the X-rays, appear to be non-polarisable.—Remarks on the preceding communication, by M. H. Poincaré. In the experiments described in the previous paper, the kathode rays have to traverse a piece of card. It has still to be shown that this card does not give out X-rays.—Researches on the principles of vegetable digestion, by M. V. Poulet. The carefully-cleaned root-hairs of a number of plants gave, on pulverising and extracting with dilute acid, traces of ferrous tartrate. This appears to play an important part in the process of vegetable digestion; and it is suggested that, in the absence of iron in the soil, it is the non-formation of this salt which causes etiolation: that chlorophyll itself in the pure state contains no iron, being now well established.—On a new property of the corpuscle of the silk-worm disease, by M. J. M. Krassilschtchik.—On the heterogamic fertilisation of the algæ *Ectocarpus secundus*, by M. C. Sauvageau.—Alteration in the elimination of phosphates, under the influence of the Röntgen rays, by M. L. Lecercle. The rate of elimination of phosphorus appears to be increased.

NEW SOUTH WALES.

Linnean Society, June 24.—Mr. Henry Deane, President, in the chair.—A new family of Australian fishes, by J. D. Ogilby. In this paper the author proposed to segregate in a new family, under the name *Melanotæniidæ*, certain small fresh-water percesocoid fishes belonging to the Austrogæan region, which differ from all other members of that group by the structure of the first dorsal fin, which consists of a single stout and pungent ray followed by two or more flexible unarticulated rays; by the thoracic insertion of the ventral fins, &c.—New genera and species of Australian fishes, by J. D. Ogilby.—On the Australian *Clivinides* (Fam. *Carabidæ*), by T. G. Sloane. Thirty-one new species of *Clivina* were described, bringing the total for Australia up to eighty-three, divisible into thirteen groups.—On the bag-shelters of certain lepidopterous larvæ of the genus *Teara*, by W. W. Froggatt. A general account is given of the curious bag-like diurnal shelters fabricated by the gregarious larvæ of moths of the genus *Teara*, with particulars of the life-history of *T. contraria* bred from nests obtained near Sydney.—Diatomaceous-earth deposits of the Warrumbungle Mountains, by Prof. T. W. E. David.—In the neighbourhood of the diatomaceous-earth deposits two formations are represented: (1) the permo-carboniferous coal measures and (2) trachyte lavas, dykes and tuffs, with which last are associated the deposits of diatomaceous-earth, and a seam of lignite. At one of the outcrops, fossil leaves (*Cinnamomum Leichhardtii*, Ettingsh.) occur on a horizon immediately above and intimately associated with the diatomaceous-earth. The latter is largely made up of diatoms (the genus *Melosira* predominating) and sponge spicules; and the age of the deposit is provisionally set down as early Eocene or late Cretaceous. The author emphasised and discussed the significance of the fact that all the diatomaceous deposits hitherto found in New South Wales occur in association with volcanic rocks.

CONTENTS.

THURSDAY, AUGUST 27, 1896.

PROFESSOR OSTWALD ON ENGLISH AND GERMAN SCIENCE.

PROF. RAMSAY has done good service by communicating to the *Times* a letter he has received from Prof. Ostwald of the highest importance at the present time, when, fortunately for us, German supremacy along many lines of applied science and the causes of it, are being at last recognised.

No one has a better right to speak on this subject than Prof. Ostwald, and the fact that we may take his communication as one made in the interests of British science makes it all the more valuable.

What he says will be no news to the readers of NATURE, because for years past we have been pointing out the rocks ahead and the steps necessary to avoid them; but our voice has been as that of one crying in the wilderness. Fortunately for us this is so no longer. The *Times* devotes a leader to Dr. Ostwald's letter, which we give in another column, but it does not appear that even the *Times* is in real touch with the actual position.

"The Germans have found that nothing pays so well as knowledge, and that new knowledge always pays in the long run. They act on this principle by maintaining a steady demand for men competent to extend the domain of theoretical knowledge, paying them well for doing it, and taking their chance of one valuable practical discovery turning up among a score that for the present lead to nothing. How good that chance is may be judged from the enormous success attending German chemical industries of all kinds. Germany controls the fine chemical markets of the world, and that means that she takes tax and toll of almost every industry in every country. How easily we might have forestalled her can be fully understood only by those who know what a splendid start we had in capital, in machinery, in control of markets, and in root ideas. Some of her most lucrative industries have been developed out of English discoveries, due to the genius of individual Englishmen, but never properly grasped and worked out by English manufacturers. Her commercial domain will go on extending, and ours proportionately shrinking, unless Englishmen become practical enough to look beyond their noses, and wise enough to believe in knowledge."

This is excellent; but then we are also told—

"For any healthy reform we want driving power, and the driving power must come from manufacturers enlightened enough to understand the secret of German success and English failure. It is industry that must endow research, not from any unpractical desire to add to the number of useless persons who know all that has been done, yet do not know how to do anything new, but from the very practical desire of manufacturers to extend their business and add to their profits."

And again:—

"There is a clamour now and again for State aid, and Dr. Ostwald's letter will, perhaps, stimulate it, because he refers to the action of the State in Germany. But the root of the matter in Germany lies in private enterprise, and it must do so here. Heaven helps those who help themselves, and the State cannot do better than observe the same limitation. When industry endows research it will be time to ask for assistance from the taxpayer. Until then State endowment of research can mean little more than throwing money away upon abstract acquirements having no real relation to the facts of national prosperity."

Let us accept for a moment that "industry," "manufacturers," and "private enterprise" in Britain at once proceed to do all that the *Times* lays at their doors. What then? Prof. Ostwald answers this question by telling us what the Prussian Government and the various German States have done and are doing for research and scientific education, above and beyond all the efforts made by German "industry," "manufacturers," and "private enterprise."

In such a competition Britain, without the State aid so amply and wisely given in Germany, is certain to lose.

It has already been pointed out in these columns, and it is worth while to re-state it, that the connection between our national greatness, our national defences, and our commerce, is universally recognised, and that the State spends, and properly spends, tens of millions a year, the protection of our commerce being assigned as one of the ostensible reasons.

But another thing which as yet is not generally recognised is that so surely as our national greatness is based upon our industries, as surely in the future must our industries be based upon science.

It is clear, therefore, that if in other countries the advancement of science is the duty not only of individuals, but of States, mere individual effort in any one country must be crushed out in the international competition which is growing keener and keener every day.

Taking things as we find them, we spend tens of millions a year to protect our commerce which is a measure of our industries; while the basis of these, science, is to remain unprotected, unorganised, and unaided, except by local efforts and the action of individuals.

Surely such a contention cannot be seriously maintained—such inconsistent action can have no logical basis. The real remedy lies in consistently organising both our peace and our war forces, as Huxley pointed out many years ago. We have now a War or Industries-protecting Council: by the side of it we want a Peace or Industries-producing Council; in other words, a strong Minister of Science, who shall have as complete a staff of men of science to advise him as the President of the War Council finds himself provided with in the heads of the Army and Navy Departments.

Only in this way can Germany's flank be turned. If it were only a question of ironclads how readily everybody would agree.

Another part of Prof. Ostwald's letter, for which thanks are due, is that in which he points out that in Germany research is as important an engine in Education as it is in a Chemical Works; so that again the call upon "private enterprise" is not sufficient.

Here, of course, the whole question of our University organisation is raised. We cannot pursue it now, but we may quote a pregnant passage from Prof. Fitzgerald's letter, also printed elsewhere—

"The most serious cause of complaint of modern society against the old universities is that they have so controlled

the education of the wealthy classes of the community, that the landed and professional classes have been educated apart from the commercial and industrial classes, to the very great injury of both."

This is the reason that the true condition of things has not been appreciated long ago. It is not understood, and therefore it is not believed. Our political leaders, the permanent chiefs of the various public departments, have not the slightest idea what all this fuss is about, because their education has been entirely apart from those regions of thought and work in which in the future the peaceful battles of the world will be fought and won; if not by us, then by others, for fighting there must be.

No better argument could be found for the establishment of a ministry and council of science than was afforded by two speeches delivered some little time ago by the Duke of Devonshire on matters connected with scientific education, and of which condensed reports were given in NATURE at the time. The Duke candidly confessed at Birmingham that he was not placed at the head of the educational and scientific affairs of the country on account of any special knowledge of the subjects, for "his knowledge of science and art could be compressed into two nutshells." It is not our desire to utter one word against the Duke of Devonshire for his candour; he has shown that he is interested in technical education, and has on more than one occasion assisted the work of science. But what we do criticise is the political system which does not consider it necessary that the educational and scientific welfare of the country should be the business of those who are able to appreciate the work done, to see the necessity of reforms, and to know the directions in which developments should take place. In almost every other country the State or Government has official men of science among its servants, and also constantly ask the advice and assistance of their academies and learned societies, when questions of technical and scientific interest are being discussed; but here no such use is made, either of the societies as a whole or of the men who constitute them.

CARL VOGT.

La Vie d'un Homme: Carl Vogt. By William Vogt. 4to vol. of 264 pages, with two portraits by Otto Vautier. (Schleicher Brothers, *ex*-Reinwald. Paris, 1896.)

A PHILOSOPHER he was—there is no doubt about that; but none of the quiet sort who "leave controversy to the little world below them": he was one of the fighting portion, and while none have known him to step out of his path to avoid a skirmish, he has often gone far from his track for the mere pleasure of picking up some battle. To him life was movement, and a true account of his years should include more than the history of his scientific work. The latter has been reviewed in NATURE for May 30, 1895, and a very full account thereof has been also given by his pupil and friend, Emile Yung, in *Revue Scientifique*, dated June 22, 1895. M. William Vogt, his son, now proceeds to tell us the essentials of his life; and although the large book before us deals but slightly with the scientific features of the lamented naturalist, still scientific readers will find much in it to interest them, in the way of anecdotes concerning Vogt's relations with men of his time, and letters of the latter.

Carl Vogt was born on July 5, 1817, at Giessen, in Germany, the eldest of nine children. Celtic blood was predominant in his veins, not Germanic, and much in his character and wit was distinctively Celtic. The son of a distinguished physician and professor, Carl had an uneventful youth. To put it short, he was lazy, and Gall could certainly not locate the "bump of respect" or of submissiveness on that head. His father was assured that the masters allowed him to pass from class to class, each year, only to get rid of this turbulent and undisciplined pupil; and it is well known that the aforesaid "bump" never grew. After the school-days, Carl was sent to the medical faculty, where he did more fighting and duelling than reading or study, and entered Liebig's laboratory. He was engaged in an investigation of the amniotic liquid (published in Müller's *Archiv*, 1837), when an event occurred which stands at the basis of all Vogt's political troubles. A law student, implicated in the Marburg plot, and a republican, begged of Vogt to help and conceal him, as the police were in search of him. Vogt—a nephew of the three republican brothers Follenius—complied immediately, and hid his fellow-student in his own room, although the next day it was officially announced that five years' imprisonment in a fortress was the penalty for such offence. A week elapsed, quietly, when one day, Liebig took Vogt aside. Liebig knew the facts, and had heard that the police also were informed; it was high time for Vogt to run. At once Vogt went home, and the same evening the refugee and himself left, in opposite directions, early enough to avoid being captured. Carl Vogt fled to an uncle of his, near Darmstadt, and spent a few weeks there, disguised by his uncle—an inspector of forests—as a forest official, and in this character taking part in the chases of the very *Gross-Herzog* himself, whose police were after Vogt. Some weeks later, he managed to cross the Rhine, and, with the help of friends, to put his feet on the French soil; he was then out of trouble. His father desired him to pursue his medical studies, and in 1839 he graduated in Bern *maxima cum laude*. But little he cared about medical art. Valentin, the physiologist and anatomist, had been interested in the young student, and wished to bring him over to zoology and physiology. Vogt took very kindly to the hints, and to Valentin's lessons, and undertook most willingly to investigate the nervous system of some South American reptiles collected by Humboldt. Hence two papers ("Neurologie von Python tigris" and "Neurologie der Reptilien," 1839-40) which are the first anatomical work of Carl Vogt, the last being more than fifty years younger. At this period, circumstances—too long to relate—put Vogt, and Edouard Desor his friend, in contact with Louis Agassiz, and they decided of Vogt's scientific future: he was bound to become a naturalist. Vogt set to work in most determined manner at Agassiz's "Poissons d'Eau douce" and at the "Embryologie des Salmonés," publishing in the meantime his

interesting paper on "Alytes obstetricans." An amusing anecdote finds its place here. One day Desor, while dictating to a young *famulus* a sentence, said, in order to surprise him: "This specimen is distinguished from others (other fishes) by this characteristic, that it has the head where the others have the tail." The *famulus* never winced. The copy went to the printing-house, and the proofs came in due time. But the wonder is that, while Desor, Vogt, and Agassiz—*deus ipse*—went over the proofs and corrected them, none noticed the absurd sentence, and it is only after fifty copies had been printed off that Desor remembered his "little joke," and stopped the proceedings. Let writers be lenient towards printers and proof-readers; such is the moral of this story.

At the same time, Agassiz, aroused to the interest of glacial studies by Venetz and Jean de Charpentier, began his historical fight against Elie de Beaumont and von Buch, and, in order to settle the matter, decided to investigate glaciers thoroughly. Thus originated the Hotel des Neuchatelois expedition, when Agassiz, Desor, and Vogt settled on the Aar glacier, and made a sort of cabin under a huge boulder which had fallen from the Schreckhorn, and upon which the names of the party were scratched, still legible, in part, a few years ago. Two summers were spent there in great activity; the "Agassiz factory," as not over-respectful Vogt used to call the association, being under its highest pressure. The Neuchatel period had its outcome—as far as Vogt alone is concerned—in the publication of "Im Gebirg und auf den Gletschern," studies on the fauna of red snow, and a severe discussion with von Buch. The latter was not convinced, but bore no grudge towards the young "Mutz" ("Mutz" is Bernese *patois* for bear, a surname given to Vogt by his friends) for his attacks, and even allowed that "aus dem kerl wird noch etwas werden."

Vogt and Agassiz were not to agree very long. To ascertain the exact cause of their estrangement would prove perhaps difficult. Ernst Haeckel has been very clear and positive on one point, however, and he denounces Agassiz as having been "the most active and clever *chevalier d'industrie* who ever worked in the field of natural history," "clever" being taken in its none too favourable sense.

Agassiz seems to have practised *Ich nehm es mit* on a large scale, taking an unfair advantage of his younger co-operators, and not giving them the credit which was due to them for their share of the work. Carl Vogt and Desor accordingly retired, and the scientific partnership of the Hôtel des Neuchatelois was dissolved. This was in 1844. Paris could hardly fail to attract Vogt, and thither he directed his steps. His friends, or masters, were Ehrenberg, the revolutionist Bakounine, von Baer, Quételet, Arago, Milne-Edwards, Leverrier, de Jussieu, and many others of equal fame. Three years were spent then, at hard work. Vogt published his investigations on the development of gasteropods, and his "Lehrbuch der Geologie und Petrefactenkunde." The latter, but little known in England or in France, was much appreciated in Germany, and much read; many editions were brought out, always kept *au courant*. The last is dated 1879. In Paris also he wrote his celebrated "Physiologische Briefe," of which Russian, German French, and Italian versions are extant. The book was as loudly praised as heartily denounced. A year ago, still, a Catholic writer compared Vogt to a "murderer" for having written it, and so clearly spoken out his materialistic creed. There is no doubt as to Vogt's sincerity, but doubt may be entertained as to the necessity of some pages in his otherwise very interesting and spirited book. "The philosopher must station himself in the middle," said Goethe. Vogt was by nature extreme. On the other hand, it must be confessed that the much-abused sentence, "Thought is about in the same relation to brain, as bile to liver, or urine to kidney," is one that no physiologist can refuse to endorse, as long as he stands only on the solid ground of facts as at present ascertained.

To the same period of life belongs "Ocean und Mittelmeer," a descriptive narrative of excursions to the seashore, mingled with scientific facts. During his summer vacations, Vogt travelled on the Mediterranean coast, and while the picturesque scenery and pleasant climate of the sun-bathed shores strongly appealed to the intense feeling of the lover of nature, the naturalist was attracted by the rich and varied fauna; he therefore decided, *hic et nunc*, to pursue his investigations; Nice was even better than Paris. Here was performed most of the work which ended in the publication of many papers on Cephalopods (with Vérany), on Siphonophora, and Ascidians. In 1846, kind Liebig, who had kept an attentive eye on his former pupil's doings, wrote to offer him a position. The Giessen University was to have a chair of Zoology; would he come and fill it? Certainly, answered Vogt. But there were difficulties. The Government was—for reasons of old, already told—no friend to the republican "Mutz," whose "Physiologische Briefe" were to many a permanent scandal; and Liebig's proposal would have been rejected, had it not been for old von Buch's and Humboldt's personal intervention. Agassiz also helped actively, and in 1847 Carl Vogt, the police-tracked student of 1837, entered Giessen as Professor of Zoology. It would seem that the *wanderjahre* were now over, and that the hot-headed young man was to settle down quietly in his chair, to grow fat and bald, and conservative, and optimistically smile upon the world, sitting down and doing nothing, or little. Such is often the case; but with Vogt, otherwise.

His first act was a scandal to the peaceful community of Giessen: he refused to shave, as university professors were required to. And then, 1848 was approaching; the storm was brewing, and how could Vogt not be attracted by the prospective trouble? A member of the dissolved *Vorparlament*—all this story cannot be abridged, so it is simply omitted—Carl Vogt was re-elected as antagonistic to the Conservative Government, and during a few days he was one of the *Reichs-regents*—part of an emperor. But the republicans were crushed by superior forces, and the revolution was checked. Vogt had to take leave—his chair was handed over to Rudolph Leuckart—and he sought a refuge in Switzerland, and shortly after in Nice. Politics were, for the time being, dismissed, and zoology again carried the day. At least, *Bilder aus dem Thierleben*, and papers on different invertebrata of the coast, went to show so much, followed by *Untersuchungen über Thierstaaten;* but even here, Vogt managed to

intersperse political allusions in biological descriptions: an unnecessary feature, to speak the truth. His innate aggressiveness had again the best of him. A year or two passed, when he received from Geneva the proposal of a botanical chair. Vogt, not feeling qualified, declined. Well, would he accept a chair of Geology and Palæontology? Willingly: and now, at last, Vogt "settled." He became a Swiss citizen, and from 1856 to the day of his death, played a not unimportant *rôle* in Swiss politics, having been repeatedly elected to the highest councils of State. He was one of the founders of the *Institut National Genevois*, and while duly attending to his professorial duties, he took an active part in the more important political and scientific discussions or quarrels of the time. He was one of those who before the sixties, ardently advocated the creation of zoological marine stations; nor could he fail, when the "Origin of Species" was thrown on the world, to become an admirer and supporter of the new theory. The principal events of his life may now be rapidly noticed. In 1861, he travelled north and visited Norway, Jan Mayen, Iceland, publishing an account of his excursion in 1862 under the title "Nord-Fahrt entlang der Norwegischen küste," &c.; in 1863, were published "Vorlesungen uber den Menschen"—translated in English, French, Italian, Spanish, Russian, Polish, Hungarian—much read, much abused, but also much approved in spite—or because—of the burning ground which they covered; and the interest Vogt took there and then in prehistoric archæology was the cause of his investigations on anthropology, later embodied in different papers: "Ueber die fossilen Menschenschädel der Diluvialbildung," "La Machoire humaine de Naulette," "Le Crane du val d'Arno." His "Vorlesungen über schädliche und nützliche Thiere" were published at about the same time. In 1865-66 he issued his important "Mémoire sur les microcéphales ou Hommes-Singes," where he considered microcephaly as a return to the condition of man's ancestor—a view much opposed by Virchow, while no definite conclusion can be said to have yet obtained. From 1867 or 1869 he wrote little, but spoke much. At that time he travelled in Germany delivering lectures on the origin of man and the Darwinian theory. "Affenvogt"—monkey-Vogt, as he was nicknamed by the people, had occasionally a hard time of it. One evening, while he was lecturing, some stones crashed through the window. "I was talking yesterday evening, gentlemen," says Vogt, picking up one of the missiles, "I was talking of our savage ancestors of the Stone age: you may perceive now, that this age is not entirely a thing of the past." And Broca, writing to him about his book on useful and injurious animals, could rightly say: "Vogt, there are many beasts in this world and of the most injurious, of which you have said nothing." . . .

Vogt's life is so very full, that it is hard to even mention its principal phases. In 1872-74 we find him actively engaged in the task of creating a medical school—a university—in Geneva, and in 1875 he succeeds, having played a very prominent part therein; at the same time he publishes his "Atlas der Zoologie," translates Gegenbaur's "Manual of Comparative Anatomy"; writes papers for a number of reviews; works at Roscoff at his "Loxosoma" and "Recherches Cotières;" and has a good fight with anti-vivisectionists. In 1879, he comes forward again with a paper on "Archæopteryx"—the second skeleton discovered. In 1884, he publishes his large book on "Mammals," illustrated by Specht; and then sets to work at his "Traité d'Anatomie comparée," with E. Yung's co-operation. A large work, and one that entailed much effort—this treatise was completed only two years ago—it was Vogt's *chant du cygne*, the last work of a very complete and active life, and one which fittingly crowned and closed his career. Carl Vogt was spared the *ante-mortem* death which too often preys upon brain-workers, and kept his mental vigour to the end.

Ever liberal in spirit and in doings, he was to the last the champion of liberal measures and laws, and the protector of the oppressed. Scientific men may regret that he did not devote more time to pure science, but he has so much contributed to ventilate the *quæstiones vexatas* of his time, and to render them intelligible to the general public; he has so liberally devoted much of his time, activity, and talent to the furtherance of measures favourable to the benefit of all, that this regret must cease to exist. Doubtless, he was often excessive in language, and his undisguised materialism made him a large number of enemies. The latter cannot fail, however, to recognise the fact that the life of this "infidel" has been one of which no orthodox man could be ashamed, and that the guiding motives of Carl Vogt's thoughts, writings, and acts were generous and elevated.

M. William Vogt's account of his father's life is most interesting, and we have not been able to do it justice in so short an account. The son has inherited much of his father's wit and hot-headedness; he writes in picturesque and not over-academical style. Some letters of Vogt's correspondents are interspersed here and there: letters from von Baer, Bunsen, de Candolle, Darwin, Gaudry, Herzen, de Quatrefages, Sir John Lubbock, Lyell, &c.; but we much regret that there are not more of those of Carl Vogt himself. The large, powerful, lion-headed naturalist had not only power at his command; wit he had also, and he knew how to use it. The slender and piercing arrow he let fly as dexterously as he wielded the sword or the battle-axe. Many still live who could testify thereto.

HENRY DE VARIGNY.

THE EASTERN TIAN-SHAN.

Description of a Journey to Western China. By G. E. Grum Grzimailo, with the aid of M. E. Grum Grzimailo. Vol. I.: Along the Eastern Tian-Shan. With map and thirty engravings. Edited by the Russian Geographical Society. In Russian. 4to. pp. 320. (St. Petersburg, 1896.)

UNDER the above title the Russian Geographical Society has issued a new addition to its splendid series of works on Central Asia, which already contains the records of the journeys of Prjevalsky, Potanin, and Pyevtsoff. The yet so little-known mountains which are described under the vague name of Eastern Tian-shan, the great desert of the Hashuñ Gobi, and the Nan-shan highlands having been the field of exploration by the brothers Grum Grzimailo during the years 1889 and 1890,

the present volume contains the records of the first year's journey along both slopes of the Tian-shan, in the oases of Guchen, Hami and Turfan. Starting from the Russian Turkestan town, Jarkent, the expedition went first to Kulj a, whence they crossed the Eastern Tian-shan, named Boro-khoro in that portion of it. To do this, they went up the steep and 8500 feet high Tsiterty, or Achal Pass, from which most beautiful views open on Lake Ebi-nor, and where the chain falls most abruptly northwards to the sandy deserts surrounding the now rapidly desiccating lake, whose altitude is only 700 feet. Then the explorers made a series of unsuccessful attempts at recrossing the Boro-khoro Mountains from north to south. Although the Torgoutes, and next the Chinese, tried to dissuade them from such a venture, they went, nevertheless, up one of the tributaries of Lake Ebi-nor, but were soon compelled to return. In their middle courses, the streams which flow from the great chain run through remarkable cañons deeply cut in diluvial deposits, and in their upper courses the cañons become mere rents between high cliffs, through which the water, rapidly rising from the melted snow, rushes as a torrent. Compelled to return, the party explored the northern spurs of the Borokhoro, vainly looking for another pass, as they slowly moved east, towards the oases of Manas and Urumchi. From this last oasis they visited the beautiful group of the snow-clad holy mountains, Bogdo-ola, which raise their peaks above a picturesque alpine lake. One fully realises, on reading the travellers' description of these forest-clad mountains, covered with glaciers, and intersected with cool alpine valleys, while barren deserts surround them, why they are so much venerated by the Mongols and considered as the seat of deity.

From the next oasis, Guchen, the party made an incursion into the sandy Dzungarian desert, and there secured at last, with no little difficulty, two specimens of the Wild Horse (*Equus przewalskii*, Poljakoff), for which Prjevalsky had vainly hunted on his last journeys. The pages given to this hunt read like a novel—so difficult and exciting was the killing of two of these cautious animals, out of a herd of seven individuals who came at night to drink in a small salt lake, and whose security was most vigilantly watched by an old male.

The first specimen secured was about ten years old. The wild horse has something in common with the Altai, Caucasian, and Finnish ponies: it is of a short stature (1·46 metre high), and has a broad chest and back, a short, massive neck, and fine legs, as elegant as those of the race-horses, ending with broad hoofs. The head seems rather heavy in comparison to the body, but the wide forehead is handsome; the line from the forehead to the nose is straight, and the upper lip covers the lower lip. The tail, whose upper part has the colour of the body, while its point is black, is longer than the tail of the wild ass, but it is not entirely covered with hair. The mane begins in front of the ears, the longest hairs being in its middle part. In the scantiness of hair, the wild horse has also something in common with the Tekke Turcomane horse; but the killed specimen had a strange-looking pair of hard whiskers, about four centimetres long, running from the ears to the chin. The wild horse has a sandy colour in summer, and light brown in winter, with nearly white parts on the abdomen; the forehead and cheeks are darker than the remainder of the body, while the end of the snout is whitish. The legs and the mane (which hangs to the left) are black; the spinal mark hardly exists, and disappears in winter. As a rule the hair is short and glossy, but somewhat curly in the foals. A good photograph of the killed horse, in profile, is given by M. Grum Grzimailo.

The manners of life of the wild horse differ from those of the wild asses—the *djighetais* and the *kulans*. They stay, in preference, in the deserts, while the latter prefer the mountain regions. They march in Indian file when they feel danger, and leave in the desert their traces in the shape of well-marked paths, as they march from their retired abodes amidst the desert hillocks to their drinking-places. They neigh exactly as our horses, while the wild asses only bray, and they have the characteristic growling of our horses. The Mongols sometimes succeed in catching young foals, but they never could tame them.

From Guchen the expedition went to Hami and Turfan, the most important centre of the region, and the work under review contains very valuable data relative to the inhabitants of these two oases. From Turfan they moved southwards, exploring the Bei-shan mountains, and coming to several interesting conclusions concerning the relations between the Tian-shan and the southern highlands, which relations will be treated more fully in the next volume. In the south of Turfan they made the remarkable discovery of the Assa depression, near Lukchun, where the barometer stood so high that, on comparing its heights with the isobars for the corresponding days in other parts of Central Asia, General Tillo concluded that the level of this depression is about 170 feet *below* the level of the ocean. The two years' barometrical observations, subsequently made by one of the members of Roborovsky's expedition, have fully confirmed the above conclusion.

A map of the region, on a scale of twenty-seven miles to the inch, accompanies the work; and certain photographs—namely, of the Bogdo-ola lake and mountains, the wild horse, and the inhabitants of the oases—are very interesting. A list of the birds brought in by the expedition, which were described by F. D. Pleske in the *Mélanges Biologiques* of the St. Petersburg Academy of Sciences (vol. xiii.), as well as a list of the Lepidopteræ collected by the author, complete the volume. Other valuable collections are still in the hands of specialists.

P. K.

OUR BOOK SHELF.

Navigation and Nautical Astronomy. By F. C. Stebbing, Chaplain and Naval Instructor, Royal Navy. Pp. vii + 328. (London: Macmillan and Co., Ltd., 1896.)

Mr. Stebbing's "Navigation and Nautical Astronomy" is the most satisfactory treatise on the subject we have yet seen. The author's experience, as a man of university attainments, a naval instructor afloat, and Admiralty examiner at Greenwich, has enabled him to produce a book that meets the practical and theoretical requirements of the modern navigator without being overladen with perplexing disquisitions or elaborate and unnecessary formulæ.

The works we have hitherto come across generally run into one extreme or the other. The first group, of which

we may take Raper's as a type, consists of excellent practical examples and methods, but is so deficient in explanation and theory that a student could not obtain any grasp of the principles involved without the assistance of some friendly tutor. This is a serious objection if we consider the need of amended methods to meet the present increased speed of ocean transit and the consequent emergencies.

The other group, following on French lines, is so lumbered with investigations of a high mathematical order as to be quite beyond the comprehension of the average sailor.

Jean, who made an attempt to combine the two, produced two volumes of good matter, but ill-arranged and cumbersome. He has, in addition to the versine method, five difficult and different ways of "clearing the lunar distance."

We are glad to see that Mr. Stebbing has taken to heart the fable of the cat and the fox, and in every astronomical problem has selected the method in general use among the advanced school, and has explained and solved his problem by that method, and that only. His book is therefore of modest dimensions, and any student of average intelligence can read it and comprehend it unaided.

The comparatively small number of first-class navigating officers is in itself a conclusive proof that the art of navigation is much more intricate than a casual run through the subject would lead us to suppose. Long experience and special advantages are necessary to graduate as an instructor in this branch of science, and we therefore all the more welcome Mr. Stebbing, who happens to possess these special requirements, as a guide to our sailors of the present and the future.

The Distribution of Rain over the British Isles during the Year 1895. Compiled by G. J. Symons, F.R.S., and H. Sowerby Wallis. Pp. 237. (London: Edward Stanford, 1896.)

MR. SYMONS'S staff of voluntary observers now numbers 3084, having grown from 168 in the year 1860. Of these observers, 2304 have their stations in England, and only 398 in Scotland—a disproportion which is to be regretted. The large number of private stations where good records of rainfall are kept, is a striking testimony to the interest taken in local meteorology.

The present report contains an interesting article on Seathwaite as a rainfall station. The first systematic records of the rainfall at that place were made in 1845, so the station attained its jubilee in 1894. The following conclusions concerning this very wet spot are stated by Mr. Symons: (1) The rainfall at Seathwaite is on the average 135 inches a year. (2) In the wettest year it has exceeded 182 inches, and may possibly reach 190 inches. (3) In the driest year it has fallen to 88 inches, and will probably never be less. (4) In one month (November 1861) more than 35 inches fell. (5) In September 1894, very little more than half an inch fell. (6) There are nine recorded cases of more than six inches falling on one day—probably there have been about a dozen—the heaviest recorded was 7·52 inches on November 26, 1861.

Several plates illustrating Seathwaite, and the positions and patterns of the rain gauges, accompany the article.

In another article in the present volume systematic percolation experiments carried on at Apsley Mills, Hemel Hempstead, are described and discussed. Gauges were sunk in sand, chalk and earth, to measure the percolation at depths of 3 feet and 5 feet in each case. The result of the whole of the observations is, with a probable error of less than 2 per cent., "that with a rainfall of 26 inches, 16 inches percolate through 5 feet of sand, and 10 inches are evaporated from it; and that 12 inches soak through 5 feet of chalk or earth, and the other 14 inches either evaporate or run off the surface." The differences between the results obtained by the gauges at 3 feet and 5 feet were very small. The loss by evaporation is found by Mr. Symons to follow very nearly the same monthly variation as that from a water surface, but is decidedly less.

There are several other articles on various branches of rainfall work, and they help to make the new issue of "British Rainfall" an interesting volume.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Total Solar Eclipse of August 9, 1896, as observed in a Cloudless Sky at Bodö.

As Bodö was considered as offering conditions not favourable for serious work, this pretty town, so easily accessible for the greater number of European astronomers, was left unprovided with any astronomical instrument. And yet that town was, during the eclipse, favoured by a cloudless sky, which could have given magnificent results. I had the good fortune to observe there the wonderful phenomenon, and to make (what was chiefly my purpose) a sketch of the general outline and the rays of the corona. I do not think that among the thousands of Norwegians who witnessed that grand spectacle there were more than twenty foreigners, almost all English and American ladies and gentlemen.

The place we selected was on a hill at Brevig on the Saltenfjord, near Bodö, which hill had been found on May 3, when the sun was as high as on August 9, to be well situated for the eclipse observation. The weather on the previous days had been fine and very promising, and on the night of August 9 was even more splendid than before. On seeing the sun rise wholly clear from behind the mountains, no trace of the smallest cloud spoiling the clearness of the sky, an enthusiastic "hurrah!" arose from the numerous gathering on the hill.

Two minutes past 4 o'clock we first saw that the sun's edge, in the northern hemisphere and on the right-hand side, was hidden by the moon. Little by little the sun's disc was covered more and more, but the amount of light did not sensibly diminish until more than three-fourths of the disc were obscured. The darkness gradually increased, for the moment of the total eclipse was approaching. How slowly the seconds seemed now to pass, and how quickly after the first moment of totality! That impressive moment occurred at 4.54. Then at once we saw the moon of almost inky darkness encircled by the white corona. The corona was not at all regular. Its most peculiar feature was the total absence of any ray or streamer in the vicinity ($\pm 25°$ W. and E.) of the sun's North Pole. Over the South Pole the corona was also a little less extensive than in the middle latitudes, where the greatest accumulations were to be seen in two enormous wings on both sides of the dark, empty space over the North Pole. The only colour I observed was the pink colour of the chromosphere around the edge of the moon (and less, also, at the sun's North Pole). In the chromosphere a few points (especially one at the left-hand, a little south from the equator) were blazing with dazzling brightness. Although the sudden apparition of Jupiter, Venus and Mercury, and, according to some observers, also of a star in the constellation Gemini, was very impressive, the darkness was not so great as I had expected, and did not hinder me in the least in beginning the sketch, which—not for want of light, but for want of the necessary calm of mind—I could only finish when all totality was over. The moments were too short and precious. I looked also an instant at the water in the fjord, and the snow-mountains on my left hand. The fjord was dull grey, the mountains pink at the bottom, and more yellowish at the top. The grass on our hill was dark olive-green.

At $4.55\frac{1}{2}$ the sudden blazing up of a white point, quickly growing to a crescent at the right-hand side of the sun, proved that totality was over. At the first glimpse of sunlight, corona, chromosphere, and planets ceased to be visible to me.

Till 5.50 the sun remained partially eclipsed. Thus we observed the sun on our steamer *Ofoden*, while returning to Bodö. But who could imagine our surprise, and the increase in our gratitude for the splendid conditions in which we had seen the eclipse, when, twenty minutes after totality was over, we saw the sky everywhere, and especially also at the sun's side, covered with heavy clouds! It was as if these clouds had been caused by some cooling effect of the eclipse. A. BRESTER, JR.

Delft, Holland, August 23.

Air Temperature during the Solar Eclipse.

SOME observations of air temperature, which I was able to make at Vadsö during the solar eclipse on August 9, are perhaps worthy of being put on record. I observed on the plateau or flat-topped hill north of the town of Vadsö, a few minutes' walk beyond Prof. Copeland's station, and at the height of 400 feet above the sea, by aneroid. None of the astronomical observers occupied quite such a high position. It was chosen in order to escape the disturbing effect of air-currents on the hill-side sloping to the fjord. The thermometer was provided with a small bulb, and hung from the tripod of a 3-inch telescope, the bulb being about 18 inches from the ground. No special precautions were taken to shield it from the sun's rays; unfortunately, they were not necessary. A light northerly breeze was blowing, and the sky was heavily clouded.

Speaking roughly, the eclipse began at 4, was total at 5, and was over by 6 o'clock. At 4.8 and at 4.18 the temperature was 44·0° F.; at 4.23, it was 43·5°; at 4.28 and 4.33, 43·2°. From 4.35 to 4.43 the sun was shining brightly, and the temperature rose to 43·3°; at 4.53 and 4.59, glimpses of the sun were caught before and after totality. The temperature from 4.48 to 4.58 was steady at 43·0°; at 5.0, it had dropped to 42·1°; from 5.3 to 5.13 it stood at 42·3°. By 5.33 it had risen to 43·8°, and at 5.48, when I ceased observing, to 45·0°.

The suddenness of the fall at, or rather immediately after, totality is very marked, the depression amounting altogether to 1·9° F. from the commencement of the eclipse, and the subsequent rise being equal to 2·9° F. to the end of the eclipse.

1 Savile Row, W., August 24. HUGH ROBERT MILL.

The Position of Science at Oxford.

YOUR correspondent "W. E. P." shows a curious ability for injuring his own side. He says that "Oxford collectively has done her best to remove any inferiority she may have had in the past" in respect of her scientific school, and further, "it would be difficult to name a body better qualified to decide what is a good general education than Convocation itself." And yet the whole tone of his letter is a practical confession that Oxford has failed in her best attempt, and that her view of general education has resulted in a practical failure to forward an essential branch of general education. The fact is Oxford's best is bad, and her ideal education is one-sided. The most serious cause of complaint of modern society against the old universities is that they have so controlled the education of the wealthy classes of the community that the landed and professional classes have been educated apart from the commercial and industrial classes to the very great injury of both. One might as well consult a committee of clergy as to the best education for a doctor, as advise with university dons as to the best education for the general community. The influence of a Pagan civilisation has created in them an ideal of life founded on contemplative learning, rather than on a Christian benevolent activity.

GEO. FRAS. FITZGERALD.

Trinity College, Dublin, August 19.

On the Notation of Terrestrial Magnetic Quantities.

AT the International Meteorological Congress to be held in Paris, a number of questions of special interest to magneticians have been proposed for discussion, among which is the following:—"The same notation should be generally employed, *H* for horizontal force, *X* for the northern component, *Y* for the western component, *Z* for the vertical force, and *V* for the potential." As the need of some uniform notation has been made apparent to me in connection with the journal *Terrestrial Magnetism*, I have been paying this matter some attention with the view of obtaining a concise and logical system for adoption in that journal.

The principle upon which I proceed is to take the first letter of a word designating a particular quantity, if at the same time it conforms with typographic requirements, such, for example, as declination, which is common to several languages. In this way I have thus far obtained the following: *D* for declination, *I* for inclination, *H* for horizontal component of force, *V* for vertical component, *F* for total force. Upon examination it will be found that these letters stand for words derived, in almost all cases, originally from the Latin and Greek languages, and with but insignificant variations in spelling, common to several of the main modern languages.

The Germans will be asked to yield a point with regard to *F*,[1] but this, as will be seen below, will be made up to them in the adoption of *G* for magnetic potential. *V* taken from the Latin *vis*, or *I* from *intensitas*, or *D* from the Greek word δύναμις, would not do for force, as they are already taken. Nor would *T* from *totus* or *P* from πᾶς answer, since the former is frequently used for time of vibration, and so in fact is the letter *P*, which stands besides for the first deflection coefficient. As I hope to be able to find a satisfactory notation for all the principal magnetic quantities, I am keeping this matter constantly in mind in adopting any particular letter. The English and French have *force*, and I have, therefore, adopted *F* for total force. As it is frequently the custom to designate angular quantities by Greek letters, I should have preferred, had it been possible, to adopt δ and ι instead of *D* and *I*, but the Greek ι is a very unsatisfactory letter from a typographical standpoint. Moreover, if found desirable later on, the small letters *d* and *i* or δ and ι can be reserved for the variations on the mean of day and on the mean of year respectively.

I think it very much to be deplored if *Z*, as above proposed, be universally adopted to designate the vertical force. It should not be forgotten that the Gaussian mode of resolving the magnetic force into northerly component (*X*), westerly component (*Y*), and vertical component (*Z*), applies to a *local* system of coordinates, not to a *fixed* system, as the layman might naturally suppose—a fact which is even apparently forgotten at times by magneticians. The mean values of these components for a complete circuit of the earth along a parallel of latitude can, in consequence, no more be *physically* interpreted than the mean *H*, for example. I am, therefore, opposed to adopting for the vertical force a letter which in no way gives evidence of the exact quantity for which it stands. *V*, on the other hand, is logically connected with *H*, and at the same time implies that the direction of the quantity that it symbolises is *local*, the direction of the vertical or plumb-line varying from point to point.

For the same reasons I am not in favour of adopting *X* for northerly component, and *Y* for westerly component. Let authors choose this method of notation, if they prefer it; but in a system suggested for universal adoption, it would seem to me that *N* and *W* would more satisfactorily meet the requirements, clearly indicating to the eye as they do the local character of the system of coordinates employed.

As a letter to designate the earth's magnetic potential, I believe none more fitting could be adopted than *G*, after Gauss, the author of this function. Gauss himself used *V*, but this letter is not sufficiently characteristic; it is used to designate many other functions in mathematical physics; and there would, moreover, be a conflict in our system, since *V* seems the most logical letter to designate the vertical force. L. A. BAUER.

Linden, Montgomery County, Maryland, August 10.

On "Hullite."

THE authors of a paper just published in the *Transactions* of the Royal Irish Academy, which is certain to be widely read, have dealt at length with the material called "hullite," urging that it is, in reality, "a hydrous glass of low specific gravity."

This paper was read on June 10, 1895, but a "note added in press" concludes as follows:—

"An abstract of this paper was published in NATURE of June 27, 1895; since then I have received, by the kindness of Prof. Cole, a paper by him on 'hullite' [reference given, *Proc. Belfast Nat. Field Club*, 1894–5, p. 1]. It contains an interesting *résumé* of the literature of the subject, and describes, quite independently, the occurrence of 'hullite' as 'a true ground-

[1] The initial letter of the German word *Kraft* is frequently used to designate the moment of inertia, and hence will not answer for force.

work to the crystalline constituents' of the rock in which it occurs."

I should not have referred to the matter had not the date of publication in NATURE been quoted in a way that suggests a sort of challenge. It seems only fair to point out that my paper was read on March 19, 1895, and that the conclusion—that the material was "an altered basic glass"—was published in two places in the *Irish Naturalist* on May 1, 1895. The full paper appeared on July 1, 1895. The two investigations, to some extent supplementing one another, afford certainly a curious case of parallelism. GRENVILLE A. J. COLE.

Royal College of Science for Ireland, August 20.

Foreign Snails in the West Indies.

Two large living specimens of *Stenogyra* (*Rumina*) *decollata*, Linn., were recently found in the garden of Dr. W. J. Branch in St. Kitts. Though familiar with the land shells of the island, having lived and collected there for many years, Dr. Branch had never come across this shell before.

These had probably been introduced accidentally as young or eggs among European plants. Tryon states that the snail is naturalised in Charleston, South Carolina. It seems to have thrived in our garden, which is very tropical, but we cannot say yet that it is naturalised.

We have tried the introduction of foreign snails into this island. *Helix* (*Dentellaria*) *josephinæ*, Fér., from Barbados, did well in a garden, but since we changed our residence it seems to have disappeared. *Bulimus* (*Borus*) *oblongus*, Mull., introduced a few years ago, also from Barbados, thrives and multiplies, but has not, so far, gone beyond the garden. It would seem, then, that the chances are against the *Stenogyra* becoming fixed in St. Kitts. The fact of its chance occurrence is, however, worth recording. C. W. BRANCH.

St. Kitts, W.I., August 2.

THE ARCTIC RECORD OF 1896.

THE triumphal progress of Dr. Nansen and his companion, Lieut. Johansen, along the coast of Norway has been interrupted by the most striking coincidence ever known in Arctic travel—the appearance of his ship the *Fram*, with all her crew in good health, and with a record of northern latitude only less remarkable than that attained by Nansen himself. On the very day that Nansen sighted the coast of Norway, the *Fram* forced her way out of the ice-pack into the open sea.

It will be remembered that Dr. Nansen's expedition was based on a theory of polar ocean-currents. The map published in NATURE for May 17, 1894 (vol. l. p. 57) shows that a current or drift was supposed to set across the Arctic Sea from the neighbourhood of the New Siberian Islands to the coast of Greenland, passing within a few degrees of the North Pole. The strongest piece of evidence for the existence of such a current was the discovery off Julianehaab, in south-west Greenland, of certain relics believed to have drifted from the *Jeannette* after her loss near the New Siberian Islands. The authenticity of the *Jeannette* relics is still in dispute. A very elaborate criticism of the evidence concerning them was published, by Prof. W. H. Dall, in the *National Geographic Magazine* for 1896 (vol. vii. p. 93), which concluded with the opinion that the whole affair was a hoax. This was warmly contradicted by a powerful Committee of the Geographical Society of the Pacific, which wound up its report on May 9, 1896, with the words: "After carefully weighing these statements and recalling the mental and physical characteristics of Dr. Nansen and the brave comrades and men who cheerfully accompany him, and the special fitness of the *Fram* to encounter ice dangers, the Committee places upon record its convictions—that the present expedition was fully warranted, and that it will return successful." A month ago these arguments were the only data on which to found an opinion as to Nansen's fate; and I was astonished to find how pessimistic were the views entertained by well-informed Norwegians, some of whom laughed heartily at me off the Nordkyn on August 10 for turning my glass on the northern horizon on the chance of sighting the *Fram*, which they believed to have been long ago crushed in the ice, and her crew perished. The unfavourable views expressed by our leading Arctic authorities on Dr. Nansen's scheme of pushing his ship into the ice and allowing her to drift with it, and on his plan of building his vessel so that she should be forced out of the ice instead of being crushed by it in case of being nipped, were loudly expressed, but they are also, fortunately fallacious. The new scheme, founded on a carefully considered hypothesis, has proved completely successful, in spite of its opposition to all the maxims of polar experience and the demands of traditional prudence.

NATURE published last week the very full telegraphic data, obtained by the *Daily Chronicle*, as to the main points of this most successful of all polar expeditions. These should suffice to satisfy public curiosity until the intrepid explorer is able to give a personal account of his work. The fact that the pole was not reached is unimportant, for it is conclusively proved that the pole may be reached with comparative ease by good ski runners, aided by a sufficiency of dogs. The additional news brought by the *Fram*, throws a good deal of new light on Arctic geography. As reported in the *Daily Chronicle's* telegram from Skjervö on August 21 and 25, the general course of the vessel was exactly that predicted by Nansen when he quitted her, viz. westward round the north of Franz Josef Land. She was left under the command of Captain Sverdrup on March 14, 1895, in 83° 59′ N., 102° 27′ E., embedded in the drifting ice about 450 miles north of Cape Chelyuskin, and 400 miles east of Franz Josef Land. By the end of February 1896, she had reached 84° 9′ N. and 15° E., a drift of 600 miles, which brought her to a point about 280 miles north of Spitzbergen. Parry in 1827 had reached 82 45′ on the same meridian by sledging over the floe until he was stopped by the rapid southerly drift of the ice. While north of Franz Josef Land the *Fram* reached its highest latitude, 85° 57′, only about 20 miles short of that attained on Dr. Nansen's sledge journey, viz. 86° 14′. Had it been possible to dispatch a sledge party from this point, the pole would most probably have been attained. From July 19 to August 12 the *Fram* was working her way out of the ice by her steam power; then gaining open water, she reached Skjervö on August 21. The minimum temperature observed was $-52°$ C., the maximum only 3° C. Neither land nor icebergs were seen, only an expanse of hummocky floe ice unbroken by any considerable stretches of open water. The ice grew to about 13 feet in thickness, and the sea ranged in depth from 1800 to 2200 fathoms.

Sir George Baden-Powell was fortunate enough to receive Dr. and Mrs. Nansen on his yacht the *Otaria* at Hammerfest, and to have the satisfaction of taking them to meet the *Fram*, with which they will probably proceed to Christiania. The enthusiasm of the Norwegian people over Dr. Nansen's success and safe return was beginning to be touched with anxiety for the fate of his equally courageous companions, which this happy reunion has effectually banished.

Until the voluminous observations bearing on almost all branches of science have been fully discussed, the true value of the results of the expedition cannot of course be known. Even now, however, some important facts are plain. Franz Josef Land is only a group of islands possibly smaller than Spitzbergen, and it does not afford the dry land highway to the pole to which at one time it was hoped to be the doorway. The absence of icebergs practically proves the absence of any extensive land in the track of the current, although it may be that the drift of the *Fram* being towards the east and not the west of Greenland, indicates the existence of a land barrier near the pole, or on the American side of it. The dream of an open polar sea must be abandoned for

ever. One of the most interesting results so far announced is the great depth of the Arctic Sea over a very large area. This accentuates the physical contrast between the Arctic and the Antarctic regions; and will probably make it necessary to adopt a greater mean depth for the ocean, and a deeper position for the line of mean-sphere level (*cf.* NATURE, vol. liv. p. 112). The general course of the *Fram*, as sketched from the provisional data, shows an altogether remarkable parallelism with Dr. Nansen's hypothetical track of the *Jeannette* relics, and fully bears out his theory of the circulation of the Arctic Sea. A "palæocrystic sea" would appear to be possible only in conditions which give rise to eddies, or otherwise impede the normal circulation. The temperature has not been found so low as that frequently experienced in northern Siberia, so that unendurable cold can no longer be viewed as an obstacle in the way of making high latitudes.

So far as high latitudes go, Admiral Markham, in 1874, succeeded in passing Parry's position of 1827 by only 35′, or about forty miles; Lockwood, in 1882, did not get more than four miles further north than Markham; but Nansen has taken the unexampled stride of 2° 50′, or almost two hundred miles beyond the previous "record," in consequence of his simple plan of not opposing, but siding with the workings of nature. The result is a triumph of science, and a proof—if proof were needed—that scientific training, no less than courage, perseverance, and physical endurance, is necessary in a great explorer.

Apart from the voyage of the *Fram*, this summer has yielded a rich harvest of arctic exploration. The *Windward*, which left Vardö on June 29, under the command of Captain Brown, an experienced whaler, and with the aid of Mr. Crowther as ice-master, has made a remarkably quick voyage to and from Franz Josef Land. She took out Mr. W. S. Bruce and another member of Mr. Jackson's party, and brought back several whose time with the expedition had expired. The telegrams which have been received show that Mr. Jackson's party have passed the winter comfortably, and have had excellent sport; they have devoted themselves to the mapping of the region around their winter quarters, and dispatches are promised by the *Windward*, which will doubtless give particulars as to points visited and positions attained. Dr. Nansen's journey on the ice north of Franz Josef Land will be a powerful stimulus which should result in great achievements.

Mr. Andrée's balloon expedition has had to be postponed on account of delay in getting the balloon-house erected and the balloon filled, but it will certainly be renewed next year. Spitzbergen, with weekly mail-steamers, a comfortable hotel, and even a set of postage-stamps, has been largely visited by tourists during the summer; but amongst the sight-seers and sportsmen there have been several scientific men bent on serious exploration. Sir Martin Conway, with Dr. Gregory, Mr. Garwood, and Mr. Trevor Battye, have been over a large amount of new ground, and made several interesting discoveries. The geology of the islands in particular has been carefully worked up, and the results will be looked forward to with confidence. The whole party has safely returned to Norway.

Mr. Peary's expedition to the north-west coast of Greenland has been much hampered by the ice, and it is uncertain whether it will yield any scientific results. The application of the name *Peary-land* to the extreme north of Greenland, proposed by the Geographical Club of Philadelphia, has been generally approved as a tribute due to an explorer of great power and perseverance.

Prospects of Antarctic exploration are no brighter. The Belgian expedition has been postponed, and the English expedition to Cape Adare does not seem likely to start this year. There is, however, a possibility that the wave of enthusiasm in polar research, which is sure to pass over Europe during the coming winter, may float some of the existing schemes, or even move high quarters, and lead to the dispatch of a properly equipped Government expedition. However glad we should be to see a British party regaining the national prestige in the polar regions, the need for scientific research in those quarters would lead us to welcome the first who comes forward with a sane plan and a sound party, be their nationality what it may. The drift of the *Fram* has shown that the new explorer may succeed, even though he may contravene every law laid down by the old, provided he respects the law of nature of moving in the direction of least resistance, and not trying to hurry through in a season what should be the deliberate progress of years. May it not be possible that we have somewhat overestimated the necessity for naval discipline, and undervalued the power of scientific enthusiasm in polar exploration?

HUGH ROBERT MILL.

SIR WILLIAM ROBERT GROVE.

"I HAVE long held an opinion almost amounting to conviction, in common I believe with many other lovers of natural knowledge, that the various forms under which the forces of matter are made manifest have one common origin; or in other words are so directly related and mutually dependent that they are convertible, as it were, into one another, and possess equivalents of power in their action. In modern times the proofs of their convertibility have been accumulated to a very considerable extent, and a commencement made of the determination of their equivalent forces."

Thus wrote Faraday in 1845, beginning his paper "On the Magnetization of a Ray of Light and the Illumination of Magnetic Lines of Force," and the words describe admirably the subject of William Grove's great work "On the Correlation of the Physical Forces" which appeared in the following year. But as a matter of fact this famous essay had been brought into existence three years before as a course of lectures delivered at the London Institution, in which Grove then held the post of Professor of Experimental Philosophy. It was the first systematic statement of the connections between the different departments of physical phenomena, and as such was of great scientific (that is *science-making*) value. Helmholtz's magnificent exposition of the principle of conservation of energy appeared the year after, and contained as completely as was then possible that quantitative discussion referred to in the last words of the above quotation from Faraday, as being when they were written, at various points begun. These two remarkable essays may be said to form the starting-point of the modern science of energetics, of which the experimental foundation was even then being overhauled and laid still more deeply and stably by Joule. If we reflect how much has come from the principle of constancy of energy with the necessary aid of other dynamical principles (for the theory of conservation is by itself insufficient for the determination of the mode of action of physical forces), we are better able to form an idea of the value of the work done by these pioneers in exploring and mapping out the paths which appeared to lead from one province of science to another.

At the time of the publication of his essay Grove was about thirty-five years of age, having been born at Swansea in 1811. He had already accomplished a considerable amount of original work of great value. His voltaic cell, known now to all who have even the slightest knowledge of electricity, was one of several voltaic combinations which he devised, and was described first at the British Association meeting at Birmingham in 1839, and again in a paper in the *Philosophical Magazine* for October of the same year. Though the Grove battery is now superseded in most of our laboratories by dynamos, it was in

its day a discovery of no slight scientific importance. It solved in a very satisfactory way for practical purposes of experimenting the problem of how to obtain a voltaic battery of high electromotive force and moderate resistance, free from the paralysing effects of polarization when used to generate large currents for fairly long intervals of time. The battery soon became a great favourite for experiments involving heavy currents, such as the production of the electric light by means of an arc between carbon points; and it was that used by Faraday in his electro-optic experiments.

From the age of twenty-five to fifty Mr. Grove, though pursuing the profession of the Law, was actively engaged in scientific work, and at a comparatively early age was elected a Fellow of the Royal Society. Just fifty years ago he was awarded a Royal medal for his paper "On Certain Phenomena of Voltaic Ignition and the Decomposition of Water into its Constituent Gases by Heat," which formed the Bakerian Lecture for 1846. His papers are numerous and deal mainly with the phenomena of the voltaic cell, and of electrolytic decomposition generally. The subject of the polarization of gases in particular occupied much of his attention, and he discovered the well-known gas-cell, so interesting from a theoretical point of view, and especially now as being the forerunner of the modern secondary battery. Besides these Mr. Grove studied electrical discharge, the effect of light on polarised electrodes, and other subjects which, investigated with the aid of modern appliances and instruments, have yielded a rich harvest of valuable results.

The most active part of Mr. Grove's scientific career may be said to have ended about the time of his presidency of the British Association at the Nottingham meeting in 1866. His presidential address was on his favourite subject "The Continuity of Natural Phenomena," and he had then the satisfaction of finding the views he so early held now shared by all scientific workers, and illustrated by a great mass of recent scientific discovery. In 1871 he was made a Judge, and shortly afterwards received the dignity of knighthood. In 1875 the honorary degree of D.C.L. was conferred on him by the University of Oxford, and was followed in 1879 by that of LL.D. from the University of Cambridge. For sixteen years he devoted himself unremittingly to his legal duties, but in 1887, when he retired from the Bench, his former scientific interests and activity, never extinct by any means, in great measure returned. But at his now very advanced age arduous scientific work was impossible, and his contributions to scientific literature were limited to such lectures and addresses as his strength enabled him to deliver.

In the preface of his essay on the Correlation of Physical Forces, Sir Wiliam Grove represented himself as standing on the vantage ground obtained by the labours of others, and therefore as able perhaps to see somewhat further than those who had gone before. It is ever thus: the men of to-day work more surely and swiftly because such men as he have lived and worked before them. It has been given to few to witness, as did Sir William Grove, almost all the scientific progress of the nineteenth century, and it must have well rewarded his scientific spirit to see the younger generation enter into the labours of the founders of the theory of energy with so much eagerness and so great a promise of fruitful achievement.

A. GRAY.

PROFESSOR HUBERT A. NEWTON.

AT the time when the attention of astronomers is again directed to the return of the nucleus of the November meteors, the sad intelligence reaches us of the death of Prof. Newton, of Yale College, whose reputation is largely connected with the history of this shower, and who, perhaps more than any other, has advanced the position of meteoric astronomy to that it now holds. He thus rendered a great service to astronomy, and had he no other claims to remembrance this would ensure a grateful recollection. Prior to his historical researches the observation of meteors possessed but a languid and feeble interest, lacking that coherence and purpose which method, founded on a suggestive hypothesis, alone can give. The collection and discussion of the original accounts of thirteen meteoric displays, all of a similar description, and distributed over a period of more than nine hundred years, demonstrated the permanent character of the phenomenon, rendered prediction possible, and invited hopeful inquiry. The fact that he left the inquiry incomplete scarcely diminishes the extent of his service, since he showed that the problem came within the range of celestial dynamics, and he at once indicated the method and supplied the means which it was certain would be effective in the hands of a master of profound and subtle analysis. It is not necessary to pursue the subject further, or to more than mention the interest subsequently added to meteoric inquiry by the discovery of Schiaparelli and others working in this fruitful field; the impulse had been given, and the subject of shooting-stars became vividly and permanently a subject of astronomical notice.

Prof. Newton's connection with the observatory of Yale University has been long and honourable. Perhaps one is not quite justified in calling him the Director of the Yale Observatory, but his position seems rather difficult to define as the Secretary to the Board of Managers, who annually present a report to the President and Fellows of Yale College. For two years, 1882–4, he certainly held the position of Director; but he seems to have preferred his old position of Secretary, leaving the head of each department to make a separate report. There can be no doubt, however, but that his was the directing mind, and determined the character of the observatory. It was while he held the position of titular chief that the heliometer, which in the trained hands of Dr. Elkin has proved itself of such value, was mounted, and probably it was his suggestion that the observatory should possess an instrument of exact measurement rather than one of those gigantic equatorials, which elsewhere in America have appealed to the fancy, and satisfied the ambition of the millionaire. Certainly he subscribed liberally to the guarantee fund which ensured its use by a skilled astronomer, and the work that has issued from the observatory under his management, whether it be parallactic inquiry or stellar triangulation, has amply justified the expenditure, and placed the institution in the front rank of those devoted to extra-meridianal work. Not but that the utilitarian side of astronomy has also been ardently pursued at Yale. The distribution of time signals, the testing of chronometers and philosophic apparatus have long been a part of the routine work, and the observatory has worthily striven to maintain a high standard of workmanship.

Prof. Newton's services to science are by no means exhausted by the fulfilment of the duties of his chair or of the direction of the observatory. He has held the post of President of the American Association for the Advancement of Science, and been the author of many papers, generally connected with meteoric or cometary astronomy. More particularly may be mentioned his inquiry into the capture of comets by Jupiter or other planets, in which he has shown that the perturbing action of the planets on parabolic orbits of every possible inclination to the ecliptic tends to produce elliptic orbits of short period, moderately inclined to the ecliptic and with direct motion.

The Royal Society recognised the eminent services Prof. Newton had rendered to astronomy by placing his name on the roll of foreign members in 1892.

W. E. P

THE ECLIPSE OF THE SUN.

KIÖ ISLAND, BRAS HAVN,
Thursday, August 6, 1896.

BEFORE I attempt to give an account of what we have done here and of the local conditions generally, it may be well to state what, in my opinion at all events, is the most important work to be done at eclipses in the present state of our knowledge.

In looking back along the eclipse records, say till 1870, it is not a little surprising to note how the attack has varied in the importance attributed to certain of the inquiries; and how often it has happened that the chief scientific result secured at any eclipse was hardly dreamt of by the organisers of the expeditions. But when there has been this notable divergence between anticipation and actual result, the work done has proved of the greatest advantage to science. I shall not be sorry, therefore, if the following anticipations fail to include the most important advances made during the coming eclipse.

In the first place I think the records already obtained by large scale prismatic cameras have shown to everybody that these instruments are the most important ones we can employ on an eclipsed sun. They not only give us a complete chemical record, on a scale hitherto undreamt of, but they give us the positions and forms of the prominences far better than they have ever been obtained before. Nor is this all, they enable us to study under new conditions some of the conclusions arrived at in previous eclipses, and give us a means of inquiring into the possible origins of some of the phenomena already recorded by slit spectroscopes.

It is now more than a quarter of a century since bright lines were recorded in the spectrum of the dark moon. There could, of course, never have been any doubt that this was due to chromospheric glare in our atmosphere; but the moment this was conceded, the more difficult it became to determine the exact height of the solar envelopes, for if there was glare over the dark moon, how high might it not extend over the prominences?

Now one of the important points about the prismatic camera is that it is quite impossible for it to treat such a general glare as this in the same way it does any local illumination; as a result of this property any effect due to general glare which *can* be recorded by a slit spectroscope *cannot* be recorded by the prismatic camera, and so, roughly speaking, a comparison of the two records may be safely trusted to eliminate the effects of such glare.

It will be generally recognised that this is an important service to render; but there is another which, from the chemical point of view, is more important still—it enables us to localise the origins of the various radiations which build up the spectrum of the sun's surroundings, whether they be high or low.

For the first time in 1893 the corona was photographed as a ring by means of the prismatic camera in "1474" light, and apparently associated with it were other rings in the ultra-violet. The 1474 ring was best shown in the Brazilian photographs taken by Mr. Shackleton, but the others in the series taken by Mr. Fowler in West Africa. Now we find that the brightness of these coronal rings seems to depend upon proximity to the equator, and is entirely independent of the prominences. That the true spectrum of the corona will be eventually thus discerned is unquestioned, and the sooner it is done the better. This part of the attack this year has been greatly strengthened, and not only have we here prismatic cameras of 6 and 9 inches aperture, but I have equipped Mr. Shackleton with a powerful instrument for his observations in Novaya Zemlya, whither he has gone in the expedition rendered possible by the public spirit of Sir George Baden-Powell.

The large scale prismatic camera was, as I have said, introduced in 1893—that is, only three years ago. The results obtained in that year represent, therefore, only the experimental stage; at the critical moments of the eclipse—that is, at the beginning and end of totality—only snap-shots were taken. This time what is termed a dropping-plate is introduced in the programme of the 9-inch. That will be exposed, while gradually falling, from ten seconds before the end of totality to fifteen seconds after, in the hopes of catching the so-called "flash" which is supposed to represent the "reversing layer." To my mind, the reversing layer is dead and buried already, but may the fates be propitious on the 9th, and enable us to place a wreath on its tomb.

So much then, briefly, for the prismatic cameras and the pre-eminent importance of their use. I next come to another point, to investigate which an important instrument has already been set up.

In organising the work for the eclipse of 1871, stress was laid on the importance of obtaining a photograph of *all* the light radiated earthwards during an eclipse, to supplement the work of the slit spectroscopes which had to do with the light radiated by *special parts* of the solar surroundings.

This work is a thousand times more important now that the spectrum of the prominences is so clearly separated from that of the corona by the prismatic cameras, because it enables us to make a flank attack, so to speak, on the corona spectrum.

The integrating spectroscope to be used on the 9th consists of a 4-inch Taylor lens of long focus as collimator directed to the sun's place during totality in a way I will state further on; then come two prisms of 60° of dense flint, and lastly a camera of 19 inches focus. The light reflected from a dark cloud gives an exquisitely sharp and well-dispersed solar spectrum in 40 seconds. During totality a plate will be exposed for 60 seconds.

Now in this instrument, simply pointed to the sun's place, the light from the greatest area will give the brightest lines. We may therefore expect the coronal lines to be well visible; and since the prismatic cameras are certain to give us a complete record of the chromosphere and prominence spectrum, a simple subtraction will bring us face to face with the spectrum of the upper reaches of the solar atmosphere.

I next come to another matter, on which it is necessary to lay great stress. It is well known that Prof. Newcomb, in 1878, introduced into eclipse work the use of a disc, behind which the brighter lower layers of the sun's atmosphere, apparently surrounding the dark moon, were hid during the totality. The object of this is, of course, to shield the eye, and an additional precaution is to blindfold the observer till totality has well commenced.

Armed in this way, Prof. Newcomb was enabled to see long luminous extensions equalling in length several diameters of the dark moon along the sun's equator. Now since such long streamers had never been seen before, it has been imagined that they indicate a special form of corona visible at the period of minimum sunspot activity, for it was at very nearly this period that the eclipse of 1878 occurred.

But it may well be that the appearance may be due to the method employed, and that such an equatorial extension may be always there if only we can see it, and the greater the solar activity the more difficult is it to see it ordinarily, because this greater activity is always accompanied by a brighter lower corona.

Prof. Newcomb, I believe, used a disc of such a size that the brighter lower corona some 3′ above the dark moon was covered. I hope to repeat this observation, and to extend it by using several discs, one or more of which will cut off 5′.

Finally, I have a few words to say on the various features of the corona independently of the large extensions, which can best be specially dealt with by the disc observers.

Let us get photographic representations of this by all means; indeed amateurs are sure to provide them; but my own opinion is that a large telescope suited for obtaining such photographs would be much better employed with a prism in front of it.

I have no photographic telescope available, so I am forced to rely on drawings, which experience shows are better than photographs for feeble extensions. It is the fashion to ridicule these drawings, and I am free to confess that often there has been no resemblance between such drawings taken at the same place; still, all the eclipses I have seen have had coronas of very different forms; and further, the special features I recorded during the eclipse of 1878 were confirmed by the photographs.

On my way to Kiö, therefore, I determined to make an experiment, by the kind help of several of my shipmates on the Orient liner *Garonne*, to see how much the uncertainty of the result depended upon the absence of special training, and to what extent it could be eliminated.

FIG. 1.—The landing of the Exploring Party.

With this object in view, by means of a capital magic lantern which we had fortunately on board, I threw on the screen about a dozen photographs and drawings, coloured and otherwise, of various eclipses observed since 1869, describing the main points to be noted at the sun's poles, equator, &c. Finally, I threw a previously unseen corona on the screen, marking the time—I took 105 seconds—as during an eclipse.

It was amply proved that after a rehearsal or two such as this all the drawings were wonderfully similar.

This new bit of experience therefore showed that when made under good conditions such drawings become of the utmost value.

The enormous difference between the shape and brilliancy of the corona at the periods of maximum and minimum sun-spot activity was one of the revelations—the *unanticipated* revelations—of the eclipse of 1878. In that year the appearances of the corona in 1871, a year of sun-spot maximum, were fresh in my mind, and fortunately the eclipse of 1878 occurred at the period of minimum. The difference was marked in every way, and I said so. For a time the statement was disputed, nay, ridiculed, but I think everybody accepts it now. The conclusion was further intensified during the eclipse of 1886, which also took place near a minimum. In that year the eclipse happened in the morning, the observation place was Green Island in the West Indies in the middle of the rainy season, and the only thing I saw was first a cloud which formed and began to obscure the sun soon after the first contact, and grew till after totality; and next, some patches of sky away from the cloud-eclipsed eclipse. These patches swarmed with stars as on a darkish night; full moonlight was never suggested.

The sun now occupies a position in the constellation Leo, such that besides planets many stars of the first, second, third, and fourth magnitudes are conveniently situated for observation. It is obvious then that we have here, if it be properly utilised, a method of photometry easily applied, and I propose if possible to utilise it, since where doubt exists the more methods of observation we employ the better.

Such, then, are some of the points to which I attach the first order of importance. I next pass on to deal with the station selected for the observations.

The longer totality and higher sun in Japan seemed to make a station in that country most desirable, but a careful inquiry into the weather conditions showed the hopelessness of any attempt there. I was then driven to Norway, and although it was true that the totality here was short, it had to be borne in mind that a short totality in the case of a prismatic camera is really more advantageous than a long one, for the reason that the rings are more complete; the longer the totality the shorter the arc impressed on each photographic plate.

Since Dr. Common and many others had determined to observe on the north side of the Varanger Fjord, it seemed a duty to go to the south side, where the weather chances were bound to be about the same. In this case, however, a man-of-war was necessary as a base. This was a matter of utmost congratulation, for I knew how surely help could be depended upon, even in extending the area of observations.

Thanks to the intervention of the Royal Society, H.M.S. *Volage*, commanded by Captain King Hall, was ultimately detached for this duty, and my story will be very badly told if I fail to show what a debt of gratitude science owes to him and his ship's company for what they have done to secure such a record of an eclipse as has never been attempted before at a single station, and I may add that the gratitude will be none the less even if the eclipse is as efficiently clouded out as it was ten years ago.

On July 23 H.M.S. *Volage*, coming from Iceland with

most of the instruments on board, picked up at Hammerfest Mr. A. Fowler and Dr. W. J. Lockyer, who had been sent forward to erect and adjust them.

On the evening of the 24th the *Volage* arrived some seven miles south of Vadsö, and proceeded to land a party of explorers to find a suitable site for the encampment on the south side of the Varanger Fjord, which had been determined on, and also to make a survey of Bras Havn in order to find the most convenient anchorage.

After sending the party on shore, the *Volage* proceeded to Vadsö to communicate with the Governor (the Norwegian Government had already given permission to camp) as to the local weather conditions. The landing party, which consisted of Lieut. Martin and Sub.-Lieut. Beal, Mr. Fowler and Dr. W. Lockyer, and several bluejackets, together with Lord Graham, who had volunteered to help, proceeded to the shore in the steam cutter, having in tow the sailing cutter and the dingy, and provided with the necessary coal, water and provisions for two days. During the three-quarters of an hour steaming from the ship they encountered a sharp squall, which would have saturated everybody if it had not been for the invaluable sou'-westers and oilskins; and it is well here to note that if one goes to the north of Norway, these should always be found in the kit together with a pair of sea-boots.

The party landed, however, safely on a small island on the eastern shore of Bras Havn, and commenced immediately to put up tents. By eleven o'clock p.m., local time, all preparations were finished. The evening turned out so beautiful that a chat round the camp fire and a drop of grog were indulged in before turning in.

The first morning on this island was not by any means cheerful, rain was coming down in torrents, and the wind whistled round the tents in a most unwelcome manner. It was decided that the survey of the bay should be taken in hand first, so Lieut. Martin, Sub.-Lieut. Beal, and Lord Graham started off in the steam cutter and commenced operations. The weather did not improve, but rather the reverse; the survey, however, made good progress notwithstanding the unfavourable conditions, but all hope was given up of finding on that day a site for the observatory on the island near by.

Sunday morning was of a different type, and work was commenced at an early hour. Mr. Fowler and Dr. W. Lockyer were landed on Kiö Island while the survey was being finished. The island of Kiö lies nearly north of Bras Havn, at a distance of about a mile and a quarter. The island itself is small, and consists of gneiss moutonnéd and polished to a wonderful degree, the surface putting on the appearance of snow in many places. The rock is covered here and there with peat. At the first glance it seemed that a suitable site for the observatory was out of the question, but on examination a very fair spot was selected which appeared to improve the more acquaintance was made with it. To economise time the sites for the concrete pillars were settled upon, and pits were dug in the peat to sound for the solid rock.

With the evening came the *Volage* from Vadsö, and her arrival was gladly hailed by the whole surveying party, as provisions had run rather short, and peat water was not regarded as a luxury. The return of the ship meant that work could now be begun in earnest, so plans were laid for an early start on the morrow. Fortunately the day proved fine, and a good start was made at putting up the large 6-inch hut. This is the time when a warship at one's back makes everything easy. The gunner turned bricklayer for the occasion, and commenced, with the help of a couple of bluejackets, mixing and setting up concrete pillars for the 6-inch and siderostat. The ship's carpenters, with their assistants, went to work with zeal with the erection of huts. Others were employed in fetching from the beach sand and stones, which were required for the concrete pillars.

Levelling the camp occupied also the time of another half-a-dozen bluejackets. At the close of the day's work the appearance of the spot had entirely changed, and the Lapps who came and watched the work seemed to be very much astonished at the alterations taking place on their island. They were, however, very friendly, and seemed to be only too pleased to help in any way they could; their assistance, however, was not required, as sufficient was at hand.

FIG. 2.—The erection of the Huts.

The following day, which proved fine, saw even greater progress; for besides erecting the 6-inch prismatic camera and siderostat, a party of bluejackets was employed in carrying stones from the beach to place on the peat covering the floor of the camp. This was done in sailor fashion, and at the word of command "stone camp," the small path leading upwards to the camp was lined with bluejackets, and buckets, full and empty, were passing up and down respectively. The scene was an interesting one to watch, and, after two hours' work, a geologist might have found a genuine raised beach.

Bad weather, however, now set in, so work was restricted for the next two days mostly inside the huts. The integrating spectroscope was put together, photographic dark slides were blackleaded to run more easily in the grooves of the cameras, and two more tents were put up to protect the 9-inch prismatic camera and integrator from the weather. The latter was composed of ship's

materials, a sail being used for the covering; the tent served its purpose well, and withstood, like the others, a heavy blow from the east.

The two wet days were followed by two very fine ones, and great advance was made.

The foregoing account will give an idea of the kind of work done up to the end of August, the day of my arrival at Kiö. It was impossible for me to join the advanced party, so I subsequently proceeded direct to Kiö in the Orient liner *Garonne*. After a delightful voyage through the most wonderful of the Norwegian fjords under perfect travelling conditions, Captain Veale was good enough to slightly alter his course so as to drop me on the day named at a point about two miles north of the island, where I was met by the boats of H.M.S. *Volage*, which soon transferred the rest of the instruments and myself to the Eclipse camp.

It will have been gathered that when I arrived at Kiö, the services of other volunteers would be of any help to us. I replied that there was so much to be done that I thought I could usefully occupy all possible volunteers if the detail of duty on board left any time for instruction and training. I was at once taken at my word, and was requested to give, in lecture form, in the forecastle that evening a statement of what was required, and why it was useful to try to do it. This was done by the help of the magic lantern, which had been kindly lent me by the *Garonne*, the deck being darkened by sails laid over booms. After it was over the Captain called for volunteers. Many at once responded to the call, and, to make a long story short, I may say that at present the number of volunteers, including officers and men, is over 70.

The first thing to be done next morning with this wealth of help was to set to and compose a programme of eclipse work beyond all precedent.

Fig. 3.—The Volunteers.

all the fixed instruments brought out had been erected and adjusted as far as possible. I put in this qualification because, of course, all star observations were out of the question, as the sun at midnight was only 4° below the horizon.

Furthermore, profiting by the good will and keenness to assist on the part of the officers, full complements of assistants had been secured for the various manœuvres requisite to obtain the greatest amount of results in the restricted time covered by the totality.

But Captain King Hall was not satisfied with this contribution to our endeavours. He inquired whether

It was at once determined to form groups to sketch the corona, to note the stars visible during totality, to note the changes of colour of the landscape, discrimination being made between cloud, sky, and land and sea surfaces; to erect several discs cutting off the lower corona to different heights; and the swoop of the shadow of the moon was not neglected.

Further, as I had brought small polariscopes, prisms, and slit spectroscopes with me, other groups evidently had to be formed to use these instruments.

Two things then obviously had to be done at once—to select the artists and to start some spectroscopic demon-

strations among the more scientific-minded. Captain King Hall at once gave up his fore cabin for the one, and Staff-Surgeon Whelan lent spirit-lamps for the other.

The first competition among the volunteer artists took place at 9 p.m. on Tuesday, 4th, that is, the day before yesterday, and was repeated last night. There were about thirty-five entries. Ten marks were given for form, ten for colour. As on the *Garonne*, after a brief description, with photographs on the screen of the things to be looked for, and the lie of the sun's axis to the horizon of Kiö, a previously unseen coloured drawing of the eclipse of 1869, and a copy of Langley's drawing of that of 1878, were thrown on the screen, and the 105 seconds given out in proper eclipse fashion by means of a stop-watch. The similarity among the drawings on both occasions, and the accuracy of the notes on colours were truly marvellous; many full marks were accorded, and as a result sixteen of the volunteers were secured for the sketches of the corona, eight for the colours of the landscape, and four for observations of the moon's shadow. For the disc parties there were six volunteers, Captain King Hall himself taking charge of the first. For this work keen eyesight was, of course, of the first importance. The drill I had suggested for the officers of the Training Squadron is adhered to, the real observer being blindfolded till 10 seconds after the beginning of totality.

Of the Spectroscopic Classes little need be said; they include nine volunteers, and work has already begun.

The distribution of work among our party is now as follows:

Fixed Instruments.

1. 6-inch prismatic camera	5
2. 9-inch " "	6
3. Integrating spectroscope	4
4. Discs	6
5. 6-inch grating spectroscope...	6

Other Observations.

6. $3\frac{3}{4}$-inch telescope	2
7. Sketches of corona	16
8. Colours of landscape	8
9. Moon's shadow	4
10. Slit spectroscopes	4
11. Prisms for rings	2
12. Polariscope	2
13. Timekeepers	3
14. Contacts	4
15. Thermometers	6

Thus making a total of 78.

Fig. 4.—The Officers of H.M.S. *Volage*.

Three main stations were next fixed upon: Kiö, as headquarters; an island lying between Kiö and the *Volage*, on which a signal station has been erected to convey messages to and from the ship; and finally the top of the majestic cliff near which the ship was lying.

Before I pass from this part of the subject, it may be stated that the volunteers are from almost every rating. Besides the officers there are—I name them in the order in which they appear in the muster rolls of the various parties—petty officers, signalmen, marines, A.B.s, ordinary seamen, stokers, blacksmiths, shipwrights, engine-room artificers, and boys.

Very many inquiries were made at the various stopping-places in the north of Norway concerning the chances of fine weather in the neighbourhood of Vadsö. The English Consul at Hammerfest, where H.M. *Volage* picked up Mr. Fowler and Dr. W. Lockyer, informed them that the question of clear or foggy weather depended almost entirely on the direction of the wind. An east wind at Vadsö meant foggy weather, a west wind fine; the reverse was the case at Hammerfest. It was also mentioned that the south side of the Varanger Fjord seemed to be more free from fogs than the northern shore. The news seemed very encouraging, since it was proposed from the beginning to settle on the southern side. It was also made manifest that it would be unwise to select an elevated spot, since clouds and mists often were seen hanging about at 100 feet and over, while the lower levels rema ned clear. The experience, gathered from the first few days spent on the southern shore, did not, however, bear out very exactly the Hammerfest information. The 24th and 25th were both miserably wet days, and yet the wind was blowing hard the whole time from the north-west. The following two days were very fine and hot, the wind coming from the eastward. But the view as to the necessity of a low elevation has been quite justified by what has taken place here.

When mists were prevalent, Kiö has always been better off than the surrounding country. The hills to the south-east and south-west have often been wrapped in mists, while the eastern horizon at the camp has been as clear as a bell. So far we have only experienced one fog.

The weather so far has seemed to have a two-day period, two fine days following wet days. The 29th and 30th were wet and windy days, while the two following ones were moderately fine. On the s.s. *Garonne* I had an opportunity of consulting two pilots well acquainted with the Veranger fjord, and both informed me that the characteristic feature of the weather was that the mornings were fine and the sky was overcast later. This has so far in the main proved accurate. The eastward horizon (we have a sea horizon) has been nearly always clear in the earlier part of the morning, *i.e.* about six a.m., while towards six p.m. it was invariably cloudy. This gives us good encouragement, and make our chances of fine weather at the time of the eclipse very hopeful. And it may be stated, further, that the chances are that even if the eclipse morning proves misty, our place of observation will be the best available, and only clouds will prevent a successful issue.

J. Norman Lockyer.

(*To be continued.*)

NOTES.

Sir George Baden-Powell did science a very important service when he conveyed a small party of observers to Novaya Zemlya to record the characteristics of the eclipse of August 9. Mr. Norman Lockyer points out in the *Times* that, thanks to this timely aid, the failures in Norway and Japan are much less disastrous than they otherwise would have been. He has received a code telegram from Mr. Shackleton, one of his assistants who accompanied Sir G. Baden-Powell, stating that results just short of the best possible have been obtained. The programme of work arranged for Novaya Zemlya included a series of twenty-two photographs with the prismatic camera (that is, a long photographic camera with two large prisms of 60° in front of the lens). The exposures were to begin thirty seconds before totality, and were to end shortly after it. They varied from snap-shots to forty seconds. The times of exposures were arranged to secure specially the spectrum of the corona. Besides this work, to which the highest value is attached, three photographs of the corona were to be obtained with a long focus telescope of 4-inch aperture. It is a matter of congratulation that these instruments have been utilised, and as Dr. Stone, who also accompanied the party, was probably equally successful in making observations, we may say that the eclipse has been saved from entire failure, so far as British astronomers are concerned, by Sir G. Baden-Powell's assistance. As to Russian observers, a Reuter telegram from St. Petersburg, August 20, says:—"The Russian astronomical expedition, which was sent to the north of Finland to observe the solar eclipse, telegraphs from Tornea that, owing to the magnificent weather which prevailed at the time, ten good photographs of the corona were obtained by means of three different apparatus. The Hydrographical Department has received a telegram from General Baron Maidelicheff, of the Saghalien astronomical expedition. The message, which was despatched from Cape Notoro, the south-western extremity of Saghalien, states that the observation of the eclipse was fairly successful, and that, although the sky was cloudy, two photographs of the corona were obtained. Some magnetic variations were noticed during the eclipse."

At the moment of going to press, the following details have been received from Mr. Shackleton, with reference to his observations at Novaya Zemlya:—"I obtained about eight photos during totality. The most successful are those at the beginning of the eclipse, also at the end and the long exposure near mid-totality. The two photos near the beginning of totality are very interesting: the one nearest the time of the beginning of totality shows, I think without doubt, as many bright lines as there are in the Fraunhofer spectrum with the same instrument, so in all probability we have succeeded in photographing the 'reversing layer.' The plate at the end of totality also shows a great many lines, but not as many as at the beginning; probably they are the same as those photographed by Mr. Fowler in the metallic prominences of 1893—certainly most of them are. The long exposure near mid-totality gives a good ring at 1474 K, and also one near K (3969 λ), and several other fainter ones. The spectra are not so extensive in ultra-violet lines as those of 1893, probably because of the cloudy state of the sky. The corona-photos have also come out very well." We propose to refer more fully to the Novaya Zemlya observations in an article in our next issue.

The Royal Society was represented at the funeral of Sir John Millais, on Thursday last, by Dr. Michael Foster and Sir Joseph Fayrer. Among other scientific bodies, which honoured art in the person of the late President, were the Society of Antiquaries, the Royal Astronomical Society, the Linnean, Chemical, and Geological Societies, the British Museum, the Royal Geographical Society, the Institution of Civil Engineers, the Colleges of Physicians and Surgeons, and the Royal Institution of British Architects.

The success of Sir Martin Conway's expedition to Spitzbergen was noted in our issue of August 6. A Reuter's telegram from Tromsö, dated August 21, states that the whole party had arrived there on their way home. Mr. Garwood and Mr. Trevor-Battye had left the main party in Spitzbergen in order to explore Horn Sund, and they succeeded in reaching and ascending Hornsund Tind, a "marble mountain" in the middle of Southern Spitzbergen, which has hitherto only been seen from the sea. They studied the geology and glacier systems of the surrounding country, and encountered serious difficulties on account of the boisterous weather. By no means the least daring part of their journey was the return from Spitzbergen to Norway in a small steam launch of less than twelve tons, necessarily a much less seaworthy craft than a sailing boat of the same size.

A Reuter telegram states that the Danish cruiser *Ingolf* returned to Copenhagen on Thursday last from a long voyage,

under the leadership of Commodore Wandel, undertaken for the purpose of exploring the navigable waters round Iceland. The expedition, which lasted two years, was highly successful. In the southern part of Davis Strait the explorers discovered a submarine mountain range. The scientific results, especially from a hydrographical and zoological point of view, are said to be exceedingly valuable.

WE regret to announce that Prof. A. H. Green, F.R.S., Professor of Geology in the University of Oxford, died on Wednesday, August 19, at the age of sixty-four. We also notice with regret the death of Dr. Rüdinger, Professor of Anatomy at Munich Observatory; Mr. Frederick Brodie, whose name will be remembered by many astronomers in connection with drawings of Donati's comet of 1858; and Miss G. E. Ormerod, the sister of the well-known entomologist. Miss Ormerod took an active share in her sister's useful work.

HARVARD UNIVERSITY, and geology, have lost a distinguished worker by the death of Prof. Josiah Dwight Whitney. From a notice in the *Times*, we gather that Prof. Whitney was born at Northampton, Massachusetts, on November 23, 1819. He graduated at Yale in 1839, and in the following year he joined the survey of New Hampshire as assistant geologist under Mr. C. T. Jackson. Two years later he went to Europe, and pursued his studies in chemistry, geology, and mineralogy. On his return to America in 1847 he investigated the geology of the Lake Superior region, being appointed with Mr. J. W. Foster to assist in making a geological survey of the district. In 1855 he was appointed State chemist and professor in the Iowa University, and was associated with Mr. James Hall in the geological survey of that State, of which he published an account. From 1858 to 1860 Prof. Whitney was engaged on a geological survey of the lead region of the Upper Missouri in connection with the official surveys of Wisconsin and Illinois. He was appointed State geologist of California in 1860, and conducted a topographical, geological, and natural history survey of that State till 1874, when the State Legislature discontinued the work. Besides numerous pamphlets and annual reports, Prof. Whitney issued "Geological Survey of California" (six vols., Cambridge, 1864–70). In 1865 he was appointed Professor of Geology at Harvard University, and retained the chair till his death. The honorary degree of LL.D. was conferred on him by Yale in 1870. Prof. Whitney was one of the original members of the National Academy of Sciences named by Act of Congress in 1863, but he subsequently withdrew from that body. He was a member of a large number of scientific bodies, both at home and abroad. He translated Berzelius's "Use of the Blowpipe" (Boston, 1845), and he wrote a guide-book to the Yosemite (San Francisco, 1869). It is a significant testimony to his scientific eminence that Mount Whitney, the highest mountain in the United States, is named after him.

AN International Exhibition of Gardening will be opened at Hamburg at the beginning of May next, and close at the end of September. The Exhibition is intended to comprise all branches of gardening and the cultivation of all kinds of plants.

THE fourth International Congress of Criminal Anthropology was opened at Geneva on Monday, and is to last till Saturday. Great Britain is officially represented, and Mr. Francis Galton, F.R.S., is among those who are down to read papers at the Congress.

THE Paris correspondent of the *Chemist and Druggist* states that the crypt made under the principal entrance of the Rue Dutot Institute, which is to contain Pasteur's tomb, is rapidly approaching completion. At the entrance of the vault is the following inscription in French:—"Happy is he who carries within himself a God, an ideal of Beauty, and obeys it; an ideal of Science, an ideal of the virtues of the Gospel." In the interior the arches are decorated with groups of animals, surrounded by frameworks of vines, mulberries and hops. Symbolical winged figures, representing Faith, Hope, Charity, and Science, appear in the centre of the cupola, forming a highly artistic group, and one which is identified with the illustrious savant's character. It is probable that the remains of the great chemist will be transferred to the Institute from Notre Dame on December 27, the anniversary of his birth.

THE International Exhibition to be held in Brussels next year promises to be of a very important character. Though commenced as a private enterprise, it is now a national undertaking, assisted by the State, and having as its patron King Leopold, while the Count of Flanders has accepted the honorary presidency. The French Government has made a grant of £35,000; Germany has so far voted no money, but has formed a powerful commission, under the presidency of Prince Charles of Hohenzollern; the United States has made a grant; the South American Republics will, in nearly all cases, be represented, and it is expected that there will be Italian, Russian, Austrian, and Scandinavian Courts. As for this country, the Government is taking an interest in the success of the undertaking, and at its request a British Commission has been formed under the presidency of Sir Albert Rollit, and with Mr. James Dredge, one of the editors of *Engineering*, as executive commissioner. It is hoped that British science, art, and industry will be worthily represented at the Exhibition.

WITH reference to the period of extremely hot weather in the United States, a correspondent writes:—"The hot weather began on August 4, and for eight days succeeding was felt over the greater part of the United States. The deaths on Tuesday, August 11, both in New York and in Brooklyn, surpassed all previous records, but were again exceeded on the following day. In the twenty-four hours ended at noon, August 13, 374 death certificates were filed at the Bureau of Vital Statistics in New York City. Of these the cause of death given in 158 cases was sunstroke. The total number of fatal sunstrokes in eight days was 617. Coroners and undertakers have been unable to dispose of the dead with sufficient speed to protect the health of the living. Lower animals, horses, dogs and cats, have died by thousands. Over one thousand horses perished in New York City, and facilities for removing the bodies were so inadequate that many remained for days where they fell. Some of the busy thoroughfares of the city were strewn with dead horses like a field of battle. In one instance, eighteen were said to be lying in one street within a short distance of each other. Brooklyn fared somewhat better on account of its proximity to the ocean; but Chicago was stricken almost like New York City. In many smaller cities similar effects were produced, and it will be impossible ever to make an accurate statement of the total fatality. In the Central Western States, the temperature rose to 110° and 115° in structures exposed to the sun at many points, and even 125° was reported from portions of Illinois, not, of course, in shaded observation stations, but in inhabited buildings."

THE seventh annual meeting of the Museums Association, held at the latter part of July in Glasgow, was a most successful one from every point of view, and in some of its importan features it exceeded any of the previous conferences. The whole of the arrangements for the meeting were carried out by the Corporation of Glasgow, who gave a very cordial welcome to the Association, and offered them every facility for inspecting the museum schemes, some developed and others developing, which mark Glasgow out as probably one of the most advanced in the kingdom in its recognition of the important value of museums and art galleries to the people of a great community. In Kelvingrove Park the Corporation are erecting a science

and art museum of palatial dimensions at a cost of over a quarter of a million, and while thus recognising the need of a central building, adequate to the exposition of science and art in its broadest sense, they have endeavoured to meet the natural requirements of an extensive city by establishing subsidiary museums in various parks and open spaces, the latest of these being the Camphill Gallery in Queen's Park, devoted at present to special exhibitions. In his presidential address Mr. James Paton, Curator of the Galleries and Museums, gave an interesting account of their foundation and progress. The papers read at the meeting included such practical subjects as descriptive labels for geological collections, by H. Bolton. electrotypes in Natural History Museums, by F. A. Bather; Type specimens in Botanical Museums, by E. M. Holmes; Chemistry in Museums, by George W. Ord; illustrated lectures in Museums, by Thomas Rennie; the lighting of Museums, by Thomas White; and a paper by F. A. Bather, on how may Museums best retard the advance of science, in which in a satirical vein he pointed out how the storage or even exhibition of specimens is not necessarily conducive to the elucidation of their history and structure. In addition to the various Glasgow museums, the members of the Association paid a visit to Perth, on the invitation of the Lord Provost, and they there had the opportunity of inspecting, under the able guidance of Mr. Henry Coates and Mr. Alexander M. Rodger, one of the most recent, as it is the most interesting and attractive, museums of a purely local character that has ever been formed in Britain.

THE interest of Prof. Ewart's experimental stud at Penicuik, Midlothian, was increased, a few days ago, by the arrival of a hybrid between a male Burchell's zebra (*Equus burchelli*) and a mare (*Equus cabattus*). Though the mare is jet black, the foal, except over the hind-quarters, has as many bands as its zebra parent. The bands are fawn-coloured, the background nearly black. But though the hybrid by its stripes suggests the zebra, in form it closely resembles an extremely well-bred foal. Should the mare have a foal to Prof. Ewart's Arab horse "Benazrek," provided with stripes and other zebra-like features, an important step will have been made in justifying breeders in believing in Telegony, or, as it is familiarly called, "the infection of the germ." When the present hybrid colt and the hybrids expected next summer reach maturity, it will be alike interesting and important to ascertain whether they are fertile with each other, and with pure horses, zebras, and asses.

IN a very interesting paper on the geology of Novaya Zemlya (*Izvestia* of the Russian Geographical Society, 1896, i.), Prof. Chernysheff points out the difference which exists between the middle parts of the island and its southern part. The latter, which must be considered as a continuation of the Pai-kho, or northern Ural ridge, is a plateau consisting of Lower Permian deposits (Artinsk layers) stretching north-west; while in the north of Bezymyannaya Bay (72° 40′) the island consists of an Alpine region, rising to an altitude of 4000 feet, and is built up of Devonian rocks, stretching north-east, and intersected by deep transversal valleys of aqueous origin, such as Matochkin Shar, and several others. It may be added to this fundamental fact, fully established by M. Chernysheff, that we should thus find in Novaya Zemlya a repetition of what is seen further south in the Urals, which also consist of plateaus stretching north-west, and of chains of mountains having a north-eastern direction. The whole of the island has been extensively glaciated. Immense moraines have been accumulated at levels which are much higher than those on which we now find *firn*-fields in the south, and in the north big moraines are found, where there are no glaciers at the present time, or only very small ones. The glaciation of Novaya Zemlya was contemporaneous with the glaciation of North Russia, and was followed by a period of subsidence, during which an archipelago of small islands was all that remained of the big island. Terraces of marine origin, containing shells of molluscs now living in the Arctic Ocean, are admirably well developed along the shores, up to an altitude of 160 metres above the sea-level. At the present time the island is in a period of upheaval, and its glaciers are again on the increase. Large fields of *firn*, in which the ice has the same structure as in glaciers, are spread over the southern plateau; while further north, in the Alpine tracts, young glaciers are being formed; so that if the same conditions continue to prevail, the island will become again the ice wilderness it formerly was.

PROF. A W. RÜCKER contributes to the July number of *Terrestrial Magnetism* a summary of the results of the recent magnetic survey of Great Britain and Ireland, conducted by Dr. Thorpe and himself. Prof. Rücker presents his valuable summary under three heads. (1) On the accuracy of the delineation of the terrestrial isomagnetic lines. (2) On the accuracy of the determination of the local disturbing magnetic forces. (3) On the relation between the magnetic and the geological constitution of Great Britain and Ireland. Illustrations accompany the article. An investigation of magnetic disturbances during the interval 1890-95, as taken from the records of the Potsdam magnetograph, is described by G. Lüdeling. For this interval the author fails to find a marked relationship between the annual curve of sun-spot frequency and the annual variation of magnetic disturbances. There is, however, a close correspondence in the diurnal and in the annual variation of the disturbances and of polar lights as observed at Oxford.

THE mode by which light and Röntgen rays are able to bring about the discharge of an electrified surface, is discussed by Dr. Oliver Lodge in *Science Progress*. Experiments were carried out by him with the object of testing the presence of metallic particles or vapour near an electrified metal rapidly discharging under the action of light. The results lead to the conclusion "that the discharge of electricity from illuminated surfaces is not effected by evaporation of those surfaces, but that the molecules, which convey the charge, belong to something in the gas, and not to the illuminated body." It is suggested that the discharge of an electrified surface by Röntgen rays—an action which seems to be brought about by the conversion of the gas, or other insulating material, near the charged body into a conductor—is probably effected "by dissociating the substances into charged atoms which are then free to act as carriers, and speedily convey to a distance the charge of an electrified body by journeys along the lines of force. It may be that ultra-violet light acts in somewhat the same way, but not in exactly the same way." As to the nature of the rays, everything now indicates them to be transverse vibrations, and Dr. Lodge thinks their wave-lengths are not much greater than the size of atoms.

PROF. VICENTINI, whose microseismograph has been noticed several times in these columns, has recently erected at Padua an important modification of his instrument. His original microseismograph at Siena consists of a pendulum whose bob remains nearly steady during rapid vibrations, and the movements of the ground are magnified, first by a vertical lever, and still further by two horizontal levers at right angles to one another. In this form, it is most useful for giving the times of the different phases of a disturbance; but, owing to the comparatively small velocity (2 mm. per minute) of the paper on which the movements are recorded, it furnishes but little information as to the direction of the displacements. At the suggestion of Dr. Pacher, the pair of horizontal levers has been replaced by a small and very light pantagraph; the weight of the bob has also been increased from 50 to 100 kg., the length of the pendulum from 1·50 to

3·36 metres, and the velocity of the paper to about 15 mm. per minute. The diagrams are of course distorted in the direction in which the paper moves, and they no longer give the exact times of particular phases; but, acting in concert with the older form, the new microseismograph furnishes valuable data with regard to the character and direction of the pulsations. In the paper by Prof. Vicentini and Dr. Pacher, in which these changes are described (*Atti del R. Ist. Veneto di scienze*, &c., vii., 1896), two interesting diagrams are reproduced, both corresponding to very distant, but unknown, earthquakes—one on December 25, 1895, and the other on January 15, 1896.

WE have received from Dr. Joachim Sperber, of Zurich, a *brochure* of 37 pp. on the parallelogram of forces regarded as the basis of the periodic system in chemistry. After applying the principle to a number of numerical calculations, the author remarks in conclusion, that the stereochemistry of carbon and nitrogen is nothing but a case of resolution into components in different directions. The paper is published by E. Speidel, of Zurich.

AMONG the 300 species, or thereabouts, of plants which Lundström and others describe with more or less accuracy as acarophilous, no gymnosperms or monocotyledons have hitherto been included, but Dr. de Gasparis, in the *Rendiconto della R. Accad. delle Scienze fisiche e matematiche* (Naples), describes a monocotyledon *Scindapsus dilaceratus* as having *Acarus*-galls produced freely at the bases of the leaf-segments. He describes them as being produced undoubtedly as the result of puncture, and details the changes which take place in the mesophyll of the leaf, resulting in a small chamber surrounded by many layers of special cells. Although he apparently accepts Lundström's view that these *Acarus*-galls are a strict case of symbiosis, the plant profiting alike by the secretions of the *Acari*, and by the latter consuming fungus spores, &c., which otherwise might germinate upon the epidermis of the plant, he produces no evidence to show that in this particular case symbiosis exists

WE have received from the agricultural department of the Glasgow and West of Scotland Technical College a *brochure* of seventy pages, embracing reports on experiments on the manuring of oats, hay, and turnips, on finger-and-toe in turnips, and on the spraying of potatoes, conducted in 1895 by Prof. R. P. Wright and others on farms in the south-west and centre of Scotland. The results of the experiments upon the oat-crop indicate that nitrogenous manures, such as nitrate of soda and sulphate of ammonia, applied alone, retard ripening, but give large and profitable, though somewhat irregular, increases of crop; also that these nitrogenous fertilisers are more uniform and more regular in their action when applied with a soluble phosphatic manure, particularly superphosphate of lime. In the case of the fungoid disease finger-and-toe—known also as club-root or anbury—confirmation is afforded of the previously ascertained fact that liming, if done early, will benefit a crop of turnips on land where the disease is prevalent. The spreading out on lea land of diseased roots to be consumed by stock is very properly condemned. It may be mentioned that finger-and-toe is very prevalent this season, especially in Scotland and the North of England, and it is no doubt a source of serious loss; the pathogenic organism is *Plasmodiophora brassicæ*. It is difficult to understand why the spraying of the potato crop with *bouillie bordelaise*, as a check upon the potato disease, should give such indifferent results in Scotland, whilst the practice has been attended by substantial benefit in England and France, and particularly in Ireland. We quite agree that, at present, "it would be rash to draw definite conclusions" from the general results of the experiments that have hitherto been made in Scotland.

MESSRS. G. BELL AND SONS have sent us an advance prospectus of a work they are about to publish under the title "Men and Women of the Century." The work comprises a series of portraits of notable men and women who have sat to Mr. Rudolf Lehmann between the years 1847 and 1895, each portrait signed with the autograph of the sitter. There will be twelve photogravures, from paintings, and about seventy facsimile reproductions of the drawings in half-tone, some of them printed in colours, and all executed by the Swan Electric Engraving Company. Among the scientific men whose biographies and portraits are given are the following:—A. von Humboldt, Louis Pasteur, Sir Richard Owen, Prof. Virchow, Prof. Huxley, Prof. Burdon Sanderson, Prof. Mommsen, Prof. Max Müller, Prof. Du Bois Reymond, Sir William Siemens, von Ranke, Sir David Brewster, Sir Henry Bessemer, and Sir Spencer Wells. The collection will thus form an interesting private gallery of contemporary portraits. It is edited by Mr. H. C. Marillier, who contributes an introduction and the short biographical notices.

THE additions to the Zoological Society's Gardens during the past week include a Capybara (*Hydrochœrus capybara*) from South America, presented by Mr. F. W. Temperley; a —— Fox (*Canis* ——) from Nicaragua, presented by Mr. F. A. Pellas; a Black-necked Grackle (*Gracupica nigricollis*) from China, presented by Dr. Nowell; a Salt-water Terrapin (*Clemmys terrapin*) from Florida, presented by Miss Hole; two Brush Turkeys (*Talegalla lathami*) from Australia, deposited; a Yak (*Poëphagus grunniens*, ♂); an English Wild Cow (*Bos taurus* var.), a Wapiti Deer (*Cervus canadensis*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL CONSTANTS.—Some account of the completed work of Drs. Gill and Elkin on the determination of astronomical constants by means of heliometrical measurement is given in the *Bulletin Astronomique* for August. The values there given differ by minute amounts from those contained in the preliminary paper published in the *Monthly Notices* for April 1894. For Solar Parallax the following values have been derived:—

From observations of Victoria	...	8″·8013	... ±0″·0061
,, ,, Sappho	...	8·7981	... ±0·0114
,, ,, Iris	...	8·8120	... ±0·0090
Mean value	...	8·8036	... ±0·0046

The value given by the Iris measures is slightly greater than that from the other asteroids, and the suggestion is made, but not insisted upon, that this might be explained by the light of Iris being somewhat less refrangible than that of the stars with which it has been compared, a fact that Dr. Elkin has noted in the course of his observations. Prof. Newcomb has pointed out that a not impossible difference between the spectrum of the planet and star could affect the resulting parallax to the extent of two or three hundredths of a second. Since, however, the mean value of the parallax does not differ from that derived from the observations of Iris by more than the probable error, no definite conclusion can be drawn on this point.

The value of the moon's mass, derived from the discussion of the observations of Victoria is

$$\frac{1}{81 \cdot 702 \pm 0 \cdot 094} = 0 \cdot 012240 \pm 0 \cdot 000015.$$

This result is believed to be free from the effects of any systematic errors.

The Constant of Nutation is given as 9·2068″±0·0034″, a value that lies midway between the generally accepted values of Newcomb and Chandler, viz. 9·210″ and 9·202″ respectively. This satisfactory agreement again points to the successful elimination of all systematic errors.

SMALL PLANET OBSERVATIONS.—The asteroid Abundantia, No. 151, has offered for solution a very curious problem. Since its discovery in 1875, it has been observed, or at least

observations purporting to refer to that planet have been made, at seven oppositions. When these are submitted to rigorous treatment and the perturbations carefully computed, it is found that the observations in 1875, 1879, 1886, and 1887 can be represented with satisfactory accuracy, but the observations of 1881, 1885, and 1894 cannot be satisfied with the same elements. While the normal places formed from the first-mentioned four years have only nominal errors, those in the other years present the following deviations :—

1881	...	$d\alpha = + 25^s.29$	...	$d\delta = - 2' \; 19''.1$
1885	...	,, $= + 38^s.20$	...	,, $= - 2' \; 0''.8$
1894	...	,, $= + 30^s.48$	...	,, $= - 3' \; 55''.3$

The obvious explanation that some numerical error in the calculations has led to this unusual result is excluded by the detail that Lieut.-Col. von Groeben has given in his description of the processes employed (*Ast. Nach.*, No. 3372). To suggest that another small planet exists moving in a similar orbit, and at present in a very similar position in that orbit, is likely to meet with opposition. The difficulty remains, however, unexplained. The similarity of the deviations from the computed path of Abundantia, both in amount and in direction, is a suspicious circumstance which, however, does not offer a definite clue. Future observation must be looked to for the explanation of the enigma, and von Groeben furnishes an ephemeris for 1896 November, which may induce observation and supply the solution of the riddle. Photographs of the district seem to offer the most likely solution, since the existence of the hypothetical planet, probably of equal brilliancy with Abundantia, should declare itself on the photographic film at no greater distance from the real or known planet than is shown by the errors above.

CYCLES OF SOLAR ECLIPSES.—In the *Bulletin de la Soc. Ast. de France* for July 1896, p. 248, M. C. Flammarion gives the history of the recent eclipse as an example of the well-known period of 18 years 11 days, the Saros, and in the course of the paper several new points are elucidated. Thus in considering any set of solar eclipses, the constants of each are found to vary regularly according to the position in the cycle. Taking the place on the central line where an eclipse begins, the next eclipse in the cycle, after an interval of 18 years 11⅓ days, will begin at a place about 118° west longitude, while another similar period will cause the third eclipse to begin in very nearly the same longitude as the first one. When plotted on a globe, the traces of the consecutive shadows appear curiously regular in the form of a triangle round the pole.

In latitude each eclipse begins a little *north* of its predecessor; the difference is about 8° for the beginning of eclipse, 4° for the middle, and 2° for the end. Continuing, it is found that the fourth eclipse has a path almost parallel to the first, but much to the north. It thus appears that in a given region a solar eclipse will recur after an interval of three ordinary cycles, each of 18 years 11½ days.

This secondary period of fifty-four years comprising three metonic cycles, M. Flammarion thinks has been unnoticed, and the remarks that it may prove more useful than the smaller period, or Saros, in predicting solar eclipses. There appears to be a regular march of the line of totality from the south to the north pole, the time taken being ten of the long cycles, or about 540 years.

STARS HAVING PECULIAR SPECTRA.—Prof. E. C. Pickering, in *Ast. Nach.*, 3370, gives details concerning the spectra and positions of eighteen stars which have been found by Mrs. Fleming to possess peculiar spectra, giving suspicion of variability. Seven of these are set down as being of Type IV., but three only are of the normal type, the remaining four containing lines of shorter wave-length.. New evidence has been obtained regarding two objects previously announced as having peculiar spectra, in *Ast. Nach.*, vol. cxxxv. p. 195, and they are now shown to belong to a different type to that formerly given. One of these, whose position for 1900 is R.A. = 17h. 38·2s., Decl. = − 46° 3′, was thought to be a stellar object having the spectrum of a gaseous nebula, but now proves to have a faint continuous spectrum, together with *bright* hydrogen lines, H_β, H_γ, H_δ, H_ϵ, H_ζ. The bright nebular line at 5007 is absent, so that this body more nearly resembles η Carinæ. The second object has the position R.A. = 18h. 39·3m., Decl. = − 33° 27′; formerly announced as being of Type V., it now proves to have the spectrum of a gaseous nebula.

COMET BROOKS (1889 V.), 1896.—The accuracy of the revised ephemeris of J. Bauschinger, noted in NATURE, August 13, has been confirmed by an observation of the comet made by H. Kobold, at Strasburg Observatory, on August 11 (*Ast. Nach.*, 3372, p. 206). He describes the comet as being feeble, and about 0·5′ of arc in diameter; in form round, with a small central condensation. The observation is considered fairly trustworthy. As the corrections the observer gives for reducing the positions stated in the ephemeris to those actually observed are only −0·49s. and −0·7″ in R.A. and Decl. respectively, the ephemeris will need no alteration for purposes of continued search.

CONTRIBUTIONS TO THE ANTHROPOLOGY OF BRITISH INDIA.

MR. EDGAR THURSTON, the energetic Superintendent of the Madras Government Museum, has recently turned his attention from zoology to anthropology, and in his fourth *Bulletin* has published the first of what we hope will be a series of investigations on the ethnography of the Madras Presidency. Thanks to the example set by Mr. Risley, the reproach of lack of interest in the natives of India on the part of residents is now being removed, and we hope that Mr. Thurston and others will continue this extremely important line of study. The title of the memoir is "Anthropology of the Todas and Kotas of the Nilgiri Hills; and of the Brahmans, Kammalans, Pallis, and Pariahs of Madras City." A large number of measurements are published, and the paper is illustrated with twenty-one plates, many of which are excellent.

One-half of the *Bulletin* deals with that very interesting autochthonous people, the Todas, who are nearly as hairy as the Ainu, and who likewise exhibit affinities with the Australians, although their high, straight nose, and fairly regular features, give them a more pleasing appearance than the latter. The typical Toda man is above medium height (5 ft. 6¾ in.), well-proportioned, and stalwart; he is dolichocephalic (73·3), with projecting superciliary ridges. A valuable account is given of the customs and religion of these herdsmen, which supplements previously published descriptions. Morality is reduced to a very low ebb before marriage, and truthfulness is not held in great regard. The Todas are endogamous as a tribe, and even as regards some of the five clans, intermarriage between the Paiki and Pekkan clans is said to be forbidden. The buffalo sacrifice is their only purely religious ceremony; it is supposed to bring good luck, and make the buffaloes yield abundant milk. A buffalo calf is killed by a blow on the head from a piece of sacred wood; the assembled Toda men (women are not permitted to take part in the ceremony) salute the dead animal by placing their foreheads on its head. According to Breeks, the flesh must be roasted on a fire made by rubbing two sticks together, and eaten by the celebrants. That is, the divine animal is periodically killed without shedding its blood, the flesh is not sodden by boiling, and the communicants eat their divinity for the benefit of the community: save on these occasions the Todas never eat meat. Mr. Thurston, however, was informed that the flesh is given to the Kotas.

The Kotas, who are allied to the Todas, are excellent artisans, being especially skilled as blacksmiths—they also pursue agriculture; but they are universally looked down on as being unclean feeders and carrion-eaters. Their diet evidently agrees with them, as they are a hard, sturdy set of men. Several of their customs are detailed. The Todas are slightly taller (1696 mm.) than the Kotas (1629 mm.), but they have the same weight (115 lbs.). They are also broader shouldered, and, though they do less manual work, their hand-grip is considerably greater. The cephalic measurements in both average about the same (length, 19·2 mm.; breadth, 14·2 mm.; index, 74).

The short account of the measurements of forty men of each of the four Bengal castes is suggestive. It is evident that the Brahmans are here a mixed Aryan and Dravidian people; below these are the Kammalans, or artisans; still lower are the Pallis, or agriculturists; and the lowest are the Pariahs; but there are traces that these once held a higher position. Risley found the nasal index coincided to a remarkable extent with the caste rank. And here we find the same story; for these four castes it is, respectively, 76·7, 77·3, 77·9, and 80; but the Pariahs are eclipsed by the Paniyans (95·1), about whom Mr. Thurston promises us further information. There is very little difference in height between the Brahmans (1625 mm.) and the Pariahs

(1621 mm.), but the Kammalans are shorter (1597 mm.). The Brahmans are better nourished, and have broader heads (142 mm.), the other three castes averaging 137 mm.; they also have the largest hands. Taking them all round, there is not that difference between the Brahmans and Pariahs that one might expect to find; but this can be explained by racial mixture. A. C. H.

SCIENTIFIC EDUCATION IN GERMANY AND ENGLAND.[1]

IN our frequent discussions on scientific education, we have both often been struck with some points of very great difference between the English and the German way of dealing with it. As it may be asserted without national arrogance that University education is in Germany in a more satisfactory condition than in your country, you are, of course, anxious to know which of the German customs I consider most effective in bringing about this better state of things; and I will, therefore, try to point them out. Of course, I shall confine myself to the subject of natural science, and especially chemistry and physics, feeling myself unable to deal with sciences beyond my knowledge. The main point of our system may be expressed in one word—freedom—freedom of teaching and freedom of learning. The first involves for the teacher the necessity of forming in his mind a clear conception of the scope of his science, for, as he is free to choose any possible method of view, he feels himself answerable for the particular one he has chosen. And in the same way the student feels himself responsible for the method and the subjects of his studies, inasmuch as he is free to choose any teacher and any subject. One who has not seen this system in action may be inclined to think that such a system must lead to arbitrary and irresponsible methods on the side of the teacher, and to confusion on the part of the student. But the former is avoided, because at the beginning of his career the teacher is dependent for his advancement on the results of his scientific views, and is naturally anxious to improve his position in the educational world. And as for the students, they themselves impose certain restrictions on their own freedom. Most of them feel that they require some advice and guidance, and they therefore follow the usual and approved order in conducting their studies. As to the inventive man of original ideas, it has often been proved that for him any way is almost as good as any other, for he is sure to do his best anywhere. Moreover, such a man very soon excites the interest of one of his teachers, and is personally led by him, generally to the great advantage of both.

Let me illustrate these general remarks by considering the course followed by an average chemist. In his first half-year he hears lectures on inorganic chemistry, physics, mineralogy, sometimes botany, and of late often differential calculus. Moreover, the German student is accustomed to take a more or less strong interest in general philosophy or history, and to add in his *Belegbuch* (list of lectures) to the above-named *Fachcollegien* (specialised studies) one or two lectures on philosophy, general or German history, or the like. Very often there are in the University one or more popular professors whose lectures are heard by students of all faculties without reference to their special studies. The student who has heard during his stay at the University only lectures belonging strictly to his *Fach*, is not well thought of, and is to some extent looked down on as a narrow specialist. But I must add that such views are not prevalent in all faculties, and there are some—*e.g.*, the faculty of law—whose students confine themselves, with few exceptions, to attending exclusively lectures in that faculty.

In the second half-year the chemical student begins with practical laboratory work. Notwithstanding the perfect freedom of the teachers, the system first introduced by Liebig into his laboratory at Giessen is still universally adopted in German universities and technical high schools—viz. qualitative and quantitative chemical analysis, the former conjoined with simple spectroscopic work, the latter amplified by volumetric analysis. This is followed by a course of chemical preparations, formerly chiefly inorganic, now chiefly organic. Even here, a regular system is being widely developed owing to the use of some well-known text-books. Of late years this course is followed in some laboratories by a series of exercises in physical chemistry and electro-chemistry.

While these practical exercises, which last for three or four half-years, are being carried out, the student completes his knowledge of physics, mathematics, and the other allied sciences by hearing lectures and working practically in the physical and often also in some other laboratory. The exercises done, he goes to the professor and asks him for a "theme" to begin his "work"—viz., his dissertation for the degree of Doctor of Philosophy. This is the most important moment in his life as a student, for it generally determines the special line of his future career. The "theme" is usually taken from the particular branch of the subject at which the professor himself is working; but, as the scientific name and position of the professor depends, not only on his own work, but to a large extent on the work issuing from his laboratory, he is careful not to limit himself to too narrow a range of his science.

Of course it is best of all if the student selects for himself a suitable "theme," suggested to him by his lectures or practical work, or from private study of the literature of the science. But this seldom happens, for the young student is not yet able to discern the bearing of special questions, and lacks knowledge how to work them out. Sometimes (but not very often, indeed) he points out to his professor in a general way the kind of problems he would like to work at, and the professor suggests to him a special problem out of this range of subjects. During the working out of his chosen subject the student learns generally much more than he has heard at lectures. Every part of the investigation forces him to revise the scientific foundations of the operations he performs. During this time the incidental short lectures given by the professor on his daily round from one to another of the advanced students are most effective in deepening and strengthening the student's knowledge. As these explanatory remarks are generally heard not only by the student whose work has caused them, but also by a number of fellow-students working near, a fairly wide range of scientific questions are dealt with in their hearing. Often these small lectures develop themselves into discussions, and, as for myself, I judge from the frequency of such discussions between the students whether the session will turn out a good one or not. If the professor thinks the work sufficiently complete to be used as a dissertation, the student proceeds to the close of his studies. He prepares himself for the examination, which is conducted by the very professors whose lectures he has heard and in whose laboratories he has worked. This examination varies somewhat in different universities, but in no case is it either very long or extensive; indeed, it is not considered as very important. For we are all aware what an uncertain means of determining a man's knowledge and capabilities an examination is, and how much its issue depends upon accidental circumstances. Part of this uncertainty is removed by the fact that the professor and the pupil know each other, are acquainted with one another's modes of expression and scientific views. The main purpose of the examination is to induce the student to widen his knowledge to a greater extent than is covered by the subject of his dissertation; but, indeed, it happens very seldom that a student whose work is considered sufficient does not pass the examination.

We have no great fear that this system may induce a professor to treat his own pupils in too lenient a way, and so lower the standard of the Doctor's degree. There was a time when such abuses used to occur, but there very soon arose such public indignation that the abuses ceased to occur. Even at the present day similar instances occasionally occur, but, as before remarked, the position of a professor depends in such a degree upon the value of the dissertations worked out under his supervision, that such deviations from the right way correct themselves in the course of time. The most effective instrument for that purpose is the publication of all dissertations and the consequent public control over them; for this reason publication is, I believe, compulsorily prescribed in all German universities.

When the student has finished his course he is still entirely free to choose between a scientific and a technical career. This is a very important point in our educational system; it is made possible by the circumstance that the occupation of a technical chemist in works is very often almost as scientific in its character as in a university laboratory. This is connected with a remarkable feature in the development of technical chemistry in Germany—the very point upon which the important position of chemical manufacture in this country depends. The organisation of the power of invention in manufactures and on a large

[1] A letter from Prof. W. Ostwald, communicated by Prof. W. Ramsay to the *Times*, August 25.

scale is, as far as I know, unique in the world's history, and it is the very marrow of our splendid development. Each large work has the greater part of its scientific staff—and there are often more than 100 *doctores phil.* in a single manufactory—occupied, not in the management of the manfacture, but in making inventions. The research laboratory in such a work is only different from one in a university by its being more splendidly and sumptuously fitted than the latter. I have heard from the business managers of such works that they have not unfrequently men who have worked for four years without practical success; but if they know them to possess ability they keep them notwithstanding, and in most cases with ultimate success sufficient to pay the expenses of the former resultless years.

It seems to me a point of the greatest importance that the conviction of the practical usefulness of a theoretical or purely scientific training is fully understood in Germany by the leaders of great manufactories. When, some years ago, I had occasion to preside at a meeting, consisting of about two-thirds practical men and one-third teachers, I was much surprised to observe the unhesitating belief of the former in the usefulness of entirely theoretical investigations. And I know a case where, quite recently, an "extraordinary" professor of a university has been offered a very large salary to induce him to enter a works, only for the purpose of undertaking researches regarding the practical use of some scientific methods which he had been working at with considerable success. No special instructions are given to him, for it is taken for granted that he himself will find the most promising methods; only, in order to increase his interest in the business, part of his remuneration has been made proportional to the commercial success of his future inventions. From this clear understanding of the commercial importance of science by the directors of industrial establishments there science itself gains another advantage. A scientific man can be almost sure, if he wants in his investigations the help of such technical means as only great works can afford, that he will get such assistance at once on application to any work; and the scientific papers of German chemists very often contain acknowledgments, with due thanks, of considerable help they have thus obtained.

Besides these advantages for the development of scientific and technical chemistry in Germany there exists another very important factor—practical assistance from the Government. Universities are in Germany affairs of the State, not of the Empire, and in no other point has the division of the Fatherland into many smaller countries proved itself to such a degree a boon and a blessing. The essential character of the German universities, the freedom conferred by the independence of the numerous universities, is never lost. There have been hard times occasionally for the universities of one country or another; but some universities were always to be found where even in times of hard oppression liberty of teaching and learning remained complete and unaffected, and the spirit of pure unalloyed scientific research was preserved and encouraged. So this palladium of intellectual freedom has never been lost; and it regained the former influence as soon as the casual oppression ceased. In our days there is among all the separate State Governments in Germany a clear conviction of the importance of practical support being given to pure scientific research. To take one instance, in order to facilitate teaching and research in electro-chemistry (a recently developed branch of science) a suggestion by some leading practical scientific men to the members of the Government was sufficient. Upon such a suggestion a considerable sum of money was spent first by the Prussian Government for the endowment of electro-chemical chairs and laboratories in the three "polytechnic" colleges of that country. A short time afterwards it was resolved to erect at one of the universities (Göttingen) an institute for physical chemistry, and especially electro-chemistry, in the shape of a building which has just been completed. At the same time, other German countries have begun to grant to their universities and technical colleges considerable sums of money for similar purposes, *e.g.* the Saxon Landtag alone has unanimously voted half a million marks (= £25,000) for the erection of a splendid laboratory for physical chemistry at Leipzig.

You will excuse my boasting about our German management of this most important question of scientific education. It is no blind admiration without criticism, for I know by practical experience the management in other countries, and I can compare them. And it is only for the sake of science itself that I write these lines. If they should help the spread of the conviction of the incomparable practical usefulness of every support given to pure science, together with the recognition of the fact that the latter can only grow in an atmosphere of liberty and confidence, I should regard it as tending towards the progress of science itself, and destined to exercise such an influence on scientific progress as may be compared with the discovery of the most remarkable scientific fact.

THE HOMOGENEITY OF ARGON AND OF HELIUM.[1]

THE question of the homogeneity of argon has been discussed by Lord Rayleigh and one of us in their memoir on Argon (*Phil. Trans.*, A, p. 236, 1895). But at that epoch the data were not sufficiently numerous to enable us to arrive at very definite conclusions. The discovery of helium and the analysis of its spectrum by Runge and Paschen (*Sitzungsberichte d. Akad. d. Wissenschaften*, pp. 639 and 759, Berlin, 1895) lead to the thought that this body may be a mixture of two gases.

To elucidate this question we submitted these two gases to a methodical diffusion, causing them to traverse a duct of porous pipe-clay submitted on one of its surfaces to the action of a vacuum. We satisfied ourselves that we might thus effect the separation of hydrogen and helium and that of oxygen and carbonic acid, and that, by measuring the rapidity of the descent of a column of mercury introduced in the circuit of the apparatus, it is possible to arrive at a good determination of the molecular weight of various gases. We have then tried to separate argon into two parts by a method analogous to the separation of liquids by fractionated distillation.

The quantity of argon was close upon 400 c.c. The gas was then treated in the manner shown in the following scheme:—

	More diffusible.			I.		Less diffusible.
	$\frac{1}{2}$	. . . .			. . . .	$\frac{1}{2}$
II.	$\frac{2}{3}$	. . . .	$\frac{1}{3}$	$\frac{1}{3}$	. . . .	$\frac{2}{3}$
	$\frac{1}{2}$	. . . .			. . . .	$\frac{1}{2}$
III.	$\frac{2}{3}$	. . . .	$\frac{1}{3}$	$\frac{1}{3}$	. . . .	$\frac{2}{3}$
	$\frac{1}{2}$	. . . .			. . . .	$\frac{1}{2}$
IV.	$\frac{2}{3}$	. . . .	$\frac{1}{3}$	$\frac{1}{3}$	. . . .	$\frac{2}{3}$
	$\frac{1}{2}$	. . . .			. . . .	$\frac{1}{2}$

We determined the density of the two extreme portions, and found that the one which ought to be the lightest had the density (O = 10) of 19·93, and the heaviest of 20·01. The separation, if it takes place, is therefore minimal.

The same experiment executed with helium yielded other results. The density of the specimen which passed first was 1·874, and that of the gas remaining in the apparatus 2·133. A great number of fractionations did not change these figures; even the spectra of the two specimens were absolutely identical. Even the first bubbles of the lighter gas showed the same lines, with the same intensity, as the last bubbles which remained in the apparatus. There was no difference in fifty fractions.

Lord Rayleigh has had the kindness to measure the refraction of the two specimens of gas. Whilst the lighter gives the figure 0·1350 (atmospheric air = 1), the heavier had a refraction expressed by the figure 0·1524. Now these two numbers have a relation almost identical with the relation of the densities, for—

$$\frac{0{\cdot}1350}{0{\cdot}1524} = \frac{1{\cdot}874}{2{\cdot}110} \text{ in place of } \frac{1{\cdot}874}{2{\cdot}133}$$

Let us now consider what happens when we submit a mixture of the two gases to diffusion. Let us take, *e.g.*, a mixture of hydrogen with an excess of oxygen. After a sufficient number of operations we obtain pure oxygen on the one hand, and on the other a mixture of 1 part of hydrogen with 4 parts of oxygen. It will not be possible to separate this mixture into its constituents, on account of the equal diffusion of oxygen and hydrogen when thus mixed. The identity of the spectra of helium prevent us from deciding which is the pure gas and which is the mixture. Calculation establishes that if we suppose the heavier gas is a mixture, the density of the lighter, supposed pure, ought to be 1·58. Helium, lastly, if it consists of a mixture of two gases, is formed either of two gases of the densities

[1] A paper presented to the Paris Academy of Sciences on July 27, by Prof. W. Ramsay and Dr. J. Norman Collie. (Reprinted from the *Chemical News*.)

2·366 and 1·874, or two gases of the densities 2·133 and 1·580.

But although this explanation is the most suitable, there exists another which deserves our attention. The spectrum of these two fractions shows no difference. It is not probable that two gases exist the densities of which are so near each other. The different gases do not possess a refraction proportional to their densities. It seems to us that we might admit that we have effected a real separation of the light mols. from the heavy mols. The idea that all the mols. of a gas are homogeneous has never been submitted to the test of experiment. We do not know of any attempt at a separation of this kind of a gas regarded as homogeneous into two different parts. But our experiments show that this question deserves to be studied. If it can yield us similar results we must change our ideas on the nature of matter.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Marquis of Bute has signified his intention of contributing £10,000 to the University of South Wales, to be applied for the purposes of technical education in Wales, the sum to be handed over to the authorities as soon as required. The Drapers' Company have also promised £10,000 towards the fund for providing new buildings, and the Government have promised £20,000 on condition that an equal amount is raised by public subscriptions.

APROPOS of the complaint from the *Local Government Journal* referred to last week, we see in the recent report of the Somerset County Council that "manual instruction in agricultural processes has made no progress." Though some successful classes in sheep-shearing, thatching, and hedging have been held at a few centres, Committees that have endeavoured to organise instruction of this kind report, as a general rule, that they have been unable to obtain from the farmers that support and co-operation which is indispensable if the work is to be carried out successfully.

WE notice in the report of the Technical Education Committee which was adopted by the Northumberland County Council at their recent meeting, that it has been decided to renew the grant of £500 to the Agricultural Department in the Durham College of Science on the following conditions, which differ somewhat from those which obtained last session:—The college is to undertake the direction of the school of agriculture and demonstration farm in accordance with the Technical Education Committee's requirements, as well as to arrange and supervise not less than six manurial trial stations at local centres in Northumberland, and to arrange for as many as sixty lectures, examinations, or inspections in agriculture and dairy work. On the other hand, the farm in Northumberland is to be open to the students of the Durham College of Science at times which are to be specified. This mutual arrangement should prove very beneficial.

THE East Sussex Committee for Technical Instruction complain that attention is given too exclusively to elementary science teaching in the various classes throughout their county, and that scarcely any work of an advanced character is attempted. This is bad, but it will be much worse if they attempt advanced teaching too soon. A completely new form of agricultural instruction has been undertaken by the authorities of the agricultural school at Uckfield, which is maintained by this Committee. The students are taken to many of the sales of agricultural implements and produce which occur in the neighbourhood, as well as to the fortnightly cattle auctions. The idea, which is to give the students an acquaintance with current values of farm and live stock, seems to have some good in it, though considerable discretion will have to be used by the instructors to prevent erroneous notions being imbibed by the students.

THE programme of the Princeton University sesqui-centennial celebration has just been announced as follows:—Tuesday, October 20, commemorative religious services in Marquand Chapel, discourse by President Patton; reception and introduction of delegates in Alexander Hall; probably a musical concert in Alexander Hall, not yet fully arranged, and some other suitable event may be substituted. Wednesday, October 21, Alumni Day, oration and poem in Alexander Hall, Prof. Woodrow Wilson, orator; Rev. Dr. Henry Van Dyke, poet; reception by President and Mrs. Patton at Prospect; students' torchlight procession and illumination of the campus; addresses from the steps of Nassau Hall, and student songs by alumni and undergraduates. Thursday, October 22, one hundred and fiftieth anniversary day; the sesqui-centennial celebration, academic procession marches to Alexander Hall; announcement of university title; announcement of endowment secured; conferring of honorary degrees, and other appropriate ceremonies; farewell dinner to the invited guests in Alexander Hall.

THERE are, it seems, only twelve scholars at the Swanley College in Kent, including six who hold scholarships which have just been awarded. Since the Kent County Council are bound to pay for twenty pupils as a minimum, the Technical Education Committee desire a more satisfactory state of things, and have recommended an entire reconstruction of the college. Nor is everything quite what is desired in Berkshire. The lectures for teachers provided by the education authority in this county cost £550 a year, yet it is reported that there is a want of appreciation of the value of the courses on the part of those for whom they are intended. Moreover, the object for which the lectures were instituted, viz. the provision of teachers to hold evening continuation schools, has not been attained. The Committee for Technical Instruction has therefore recommended that no new students be admitted for attendance at science lectures, but that the three years of existing students (if duly qualified) be completed. It is further complained that teachers have not availed themselves of the good work which is being done at the Reading University Extension College.

THE Programme of Technological Examinations of the City and Guilds of London Institute (Whittaker and Co.) furnishes abundant information on the valuable work which the Institute is doing for technology and manual training. The programme contains the syllabuses of the sixty-six subjects in which examinations are now held (a helpful list of works of reference being given at the end of each), and the examination questions set this year. Among the changes in the Institute's programme, we notice the following:—The subject of "Brickwork and Masonry" has been divided into two, "Brickwork" and "Masonry," and a practical examination, to be held in London, has been added to each. The regulations for the examination in "Photography" have been altered. In future, all candidates will be required to pass a local practical examination before being admitted to the written examination in the ordinary grade. The syllabus in "Paper Manufacture," in "Pottery and Porcelain," in "Boot and Shoe Manufacture," in "Dressing of Skins," in "Cotton Spinning," has been re-written. In several other subjects the syllabus has been altered. Provision has been made for admitting, under certain conditions, teachers of secondary schools to the manual training examinations.

THE report of the Somerset County Education Committee for the financial year ending March 31, 1896, gives abundant evidence of the accomplishment of much good work. The plans of the Committee are laid upon a carefully thought-out basis, and reflect no small credit on the wisdom of their organising adviser. These arrangements have been the same as in previous years, with the exception of discontinuing the courses of University Extension Science Lectures, which has meant a saving of more than £1000 per annum. We are glad to notice that the Committee are able to report that the work as a whole "shows a distinct and satisfactory tendency to develop along certain well-marked and permanent lines, with a corresponding reduction in the number of classes of a more or less ephemeral character." In no case has an evening continuation school been reported to them by the inspectors as generally inefficient; and "there is a general tendency towards an increase in the average attendances" in all of the 141 of these schools. As regards the work in the secondary schools of the county, many of which have been substantially aided by the Committee, it has been rightly laid down "that the best foundation for technical instruction is a really good secondary education sufficiently comprehensive in its character to include, in addition to the ordinary English subjects, natural science, mathematics, modern languages, drawing, and some manual training, and it is with a view to place an education of this kind at moderate fees within the reach of all in the county who wish to avail themselves of it, that the County Committee gives the aid specified." It is not to be wondered at, after so sensible a declaration, that the report is able to call attention to excellent results from all divisions of their administrative area.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, June 18.—Mr. A. G. Vernon Harcourt, President, in the chair.—The following papers were read :—The action of bromine on pinene with reference to the question of its constitution, by W. A. Tilden. The author experimentally confirms his view that one molecule of pinene can combine with four atoms of bromine, and proposes a new formula for the hydrocarbon.—Preliminary note on some products from pinene tetrabromide, by W. A. Tilden and A. Nicholls.—An apparatus for showing experiments with ozone, by G. S. Newth. The author describes an apparatus for showing the action of reagents on ozonised oxygen, the reagent being introduced in such a way that the volume of the gas is not disturbed.—Note on santalal and some of its derivatives, by A. C. Chapman and H. E. Burgess. It is shown that cedrene and the hydrocarbon obtained by the action of phosphorus pentoxide on santalal are very similar but not identical.—Second note on the liberation of chlorine during the heating of a mixture of potassic chlorate and manganic peroxide, by H. McLeod. The author confirms his previous observation that the gas obtained by heating potassium chlorate with manganese dioxide contains small quantities of chlorine, but no ozone.—Polymorphism as an explanation of the thermochemical peculiarities of chloral and bromal hydrates, by W. J. Pope. The fact that the heat of dissolution of chloral hydrate is partly dependent on the length of time elapsing since solidification, is shown to be due to a change in crystalline form of the solid substance.—Explosion and detection of acetylene in air, by F. Clowes. Mixtures of air with 3—81 per cent. of acetylene are explosive ; the best method of estimating acetylene in air is based on the examination of the change occurring in a hydrogen flame when such air is passed over it.—On the occurrence of quercitin in the outer skins of the bulb of the onion (*Allium Cepa*), by A. G. Perkin and J. J. Hummel. The colouring matter present in the skin of the onion bulb is shown to be quercitin.—On the colouring matter contained in the bark of *Myrica nagi*, by A. G. Perkin and J. J. Hummel. The bark of *Myrica nagi* contains a colouring matter $C_{15}H_{10}O_8$, which the authors term myricetin ; it is probably a hydroxyquercitin.—Preliminary note on a new base derived from camphoroxime, by M. O. Forster. By treatment with methylic iodide, camphoroxime yields campholenonitrile together with the hydriodide of a new tertiary base, $C_{12}H_{19}N$; a number of compounds of the latter have been prepared.—The rotation of aspartic acid, by B. M. C. Marshall.—Synthesis of pentacarbon rings. Part iii. Condensation of benzil with lævulic acid, by F. R. Japp and T. S. Murray. Benzil and lævulic acid condense yielding two isomeric anhydrobenzillævulic or diphenylhydroxycyclopentenonylacetic acids ; the derivatives and decomposition products of these acids are described.—Absorption of dilute acids by silk, by J. Walker and J. R. Appleyard.—Position-isomerism and optical activity ; the methylic and ethylic salts of ortho-, meta-, and para-ditoluyltartaric acid, by P. Frankland and F. M. Wharton.—Double sulphides of gold and other metals, or the action at a red heat of sulphur upon gold when alloyed with other metals, by J. S. Maclaurin.—The relative weights of gold and silver dissolved by potassium cyanide solutions from alloys of these metals, by J. S. Maclaurin.—The three chlorobenzeneazosalicylic acids, by J. T. Hewitt and H. E. Stevenson. Ortho- and para-chlorobenzeneazosalicylic acids have been prepared by the action of diazotised chloraniline solution on salicylic acid ; derivatives and salts of the three isomerides are described.—Condensation of chloral with resorcinol, by J. T. Hewitt and F. G. Pope. The condensation of chloral and resorcinol yields a tetrahydroxydiphenylacetic acid and its lactone.—The atomic weight of Japanese tellurium, by Masumi Chikashigé. The tellurium of which the atomic weight has previously been determined has been obtained from metallic tellurides ; if tellurium be a compound, as has been suggested, that obtained from Japanese tellurosulphur should have a different atomic weight. The author finds, however, that tellurium from the latter source has the same atomic weight as that prepared from tellurides, and consequently concludes that this element really has a greater atomic weight than iodine.—Derivatives of camphene sulphonic acids, by A. Lapworth and F. S. Kipping. The α- and β-chlorocamphenesulphonic chlorides obtained during the sulphonation of camphor, and their derivatives, are described.—Iodoso- and iodoxybenzaldehydes, by V. Meyer and T. S. Patterson.—α-Isopropylglutaric acid, by W. H. Perkin, jun.—The action of ethylic β-iodopropionate on the sodium derivative of ethylic isopropylmalonate, by T. Z. Heinke and W. H. Perkin, jun.—The condensation of halogen derivatives of fatty ethereal salts with ketones and ketonic acids, by W. H. Perkin, Jun., and T. F. Thorpe.—The electrolysis of the salts of monhydroxy-acids, by J. W. Walker.—The action of formic aldehyde on phenylhydrazine, and on some hydrazones, by J. W. Walker.—The colouring matter of Sicilian sumach, *Rhus coriariæ*, by A. G. Perkin and G. Y. Allen. The colouring matter of Sicilian sumach is not quercitin or quercitrin, but myricetin.—The colouring matter of *Quebracho Colorado*, by A. G. Perkin and O. Gunnell. The colouring matter of querbracho is fisetin.—On asitine, the alkaloïd of *Aconitum heterophyllum*, by H. A. D. Jowett. Asitine is amorphous and non-toxic, and probably has the composition $C_{22}H_{31}NO_3$; many of its salts are described.—The action of methyl alcohol on aconitine. Formation of methyl benzaconine, by W. R. Dunstan, T. Tickle, and D. H. Jackson.—The chemical inactivity of Röntgen rays, by H. B. Dixon and H. B. Baker. The authors have investigated, with negative results, the question whether Röntgen rays are able to influence chemical change, either by starting it or by accelerating or diminishing it after it has been started by ordinary light.—Colloïdal chromsulphuric acid, by H. T. Calvert and T. Ewan.

CONTENTS.

THURSDAY, SEPTEMBER 3, 1896.

AN AMERICAN PROFESSOR.

Memoirs of Frederick A. P. Barnard, D.D., LL.D., &c., Tenth President of Columbia College in the City of New York. By John Fulton. Pp. xii + 485. (New York: published for the Columbia University Press by The Macmillan Co. London: Macmillan and Co., Ltd. 1896.)

THE name of Barnard is honourably associated with the history of education in the United States. To English readers, the best-known bearer of the name is the Hon. Henry Barnard, formerly United States Commissioner of Education, and now living in retirement at Hartford, Connecticut. As the author of numerous local and special reports, and the compiler of valuable statistics and monographs on the various aspects of public instruction; and particularly, as the editor of four or five massive volumes containing reprints of standard treatises on the philosophy and history of education in England and Germany, he has done more than any man in the American Union to promote the study of pedagogical literature.

The present volume recounts the history and doings of one who is less generally known on this side of the Atlantic—the Rev. Frederick A. P. Barnard, a versatile, fluent, and vigorous man who filled with credit many academic offices, and exercised considerable public influence, both within and without the college and university world of America. He was born in 1809, and graduated at Yale 1828, became tutor in 1829, teacher in the asylum for the deaf and dumb at Hartford and in that of New York, his own interest in children thus afflicted being greatly enhanced by the defect of hearing which troubled him through life, and which he manfully strove to fight against. In 1837 he was professor of mathematics and natural philosophy in the University of Alabama, and afterwards of chemistry, remaining in that University till 1854, when he took orders in the Episcopal Church, and became professor of mathematics and astronomy in the University of Mississippi, becoming its president in 1856. He removed to Columbia College in 1864, subsequently served as United States Commissioner to the Paris Expositions of 1847 and 1878, and wrote for the former an elaborate report on machinery and the industrial arts. His versatility and many-sided interests are well illustrated by the facts that he occasionally served as professor in literature and history, and that his published works include a treatise on arithmetic; an analytic grammar with symbolic illustration descriptive mainly of a system designed for the use of the deaf and dumb; letters on Collegiate Government, 1855; history of the United States Coast Survey, 1857; recent progress of Science, 1869; and the Metric System, 1871. Although no scientific observation or discovery of an original kind can be ascribed to him, he was a member in 1860 of the astronomical expedition to observe the total eclipse of the sun in Labrador, in 1862 he was engaged in continuing the reduction of the observations of the stars in the southern hemisphere by Gillis, and in 1863 had charge of the publication of Charts and Maps of the United States Coast Survey. He served in 1860 as President of the American Association for the Advancement of Science, and in 1872 of the American Institute. He received honorary degrees from Jefferson College, Missouri, from Yale and from Mississippi, and also that of Doctor of Literature from the University of the State of New York. During part of his life he served as editor of a review, and was a frequent contributor to newspapers and magazines, both in prose and verse.

The pious care of his widow in collecting his speeches and reports, and the facile pen of his biographer, Mr. Fulton, have produced a large volume of nearly 500 pages, which, though containing many facts illustrative of the growth of higher education in America, and much information respecting significant but ephemeral academic controversies, strikes the English reader as somewhat disproportioned to the amount of Barnard's actual achievement and force in the world. A due sense of historical perspective, and of the difference between what is temporary and what is permanent in a human life, is one of the highest and, it must be owned, one of the rarest qualifications of a biographer. Had it been possessed by the author of this volume, the narrative might with great advantage have been reduced to half its present length.

Barnard's views about the purpose of education, though not novel, showed insight and good sense.

"It has always seemed to me," he said, "to be the great, as it is the almost universal, educational mistake of our time, that children, instead of being introduced to subjects which address the perceptive faculties, and which are adapted to furnish them with a flood of novel and clearly comprehensible ideas, are usually condemned to the dreary study of unintelligible words, which impose a heavy burden on the memory, and are only apprehended after the understanding has become matured with advancing years."

He saw also, with greater clearness than many of his associates, the intellectual dangers of that "elective system" which has obtained so much favour in the States, and the confusion which would arise, especially in small colleges, "if every student were allowed to study what he chose, all that he chose, and nothing that he did not choose." He insisted with much force that the demand for such options "did not proceed from a genuine desire for special or partial instruction, but simply and solely from the ambition to obtain the college stamp of scholarship without submitting to that severe and systematic intellectual training which alone can make the scholar."

Of his resolute opposition to Slavery, and of his sympathy with the party of Union in the Civil War, notwithstanding the prevalent feeling among his neighbours in the South, the volume gives an interesting account. It was not till his removal to Columbia College in New York, that he acquired full freedom to carry into effect his views on academic organisation and reform without being hindered by quasi-political opposition or distrust. At fifty-five years of age he was elected to the presidency of that institution, which, though with an interesting history and considerable resources, had hardly entitled itself to the rank of a university. By the development of a School of Mines and the Schools of Law and of Medicine, and especially by the provision of new means and encouragement for post-graduate research, Barnard did much to

vindicate the claims of Columbia College to that rank, and to secure for it increasing repute and public usefulness. He urged on the Trustees the importance of making the College available for the advanced education of women, and succeeded after long and arduous effort in establishing what is now known as the Barnard Annexe to the College, a feminine institution practically under the care of the same professors, and aiming at the same academic course. In 1882 he took the first steps in a movement with which the name of Dr. Murray Butler has since been conspicuously associated for establishing a professorship in the literature, history, and art of Education, and for securing professional training for those students who intended to become teachers. On the whole the book, though diffuse in style and encumbered with some needless detail, is a useful contribution to educational history. It is the record of a strenuous and honourable life, of high and generous aims often obscured by discouragement, but ever kept steadily in view, and of a considerable number of experiments, both in regard to instruction and discipline, which have done much to render the solution of educational problems easier, especially in America. J. G. FITCH.

APPLIED CHEMISTRY OF NITRO-EXPLOSIVES.

Nitro-Explosives. By P. Gerald Sanford, F.I.C., F.C.S. Pp. xii + 270. (London: Crosby Lockwood and Sons, 1896.)

WE had lately under our notice a work on explosives which dealt with their manufacture more from an engineer's point of view than from that of a chemist, and consequently the various appliances were described with a detail which only a practical engineer could properly express. In the present volume the processes are placed before us exclusively from a chemist's point of view, and the appliances and machines used receive generally but a brief notice; indeed, some fifty sketches is the sum total of the illustrations covering the apparatus used in the manufacture of the numerous nitro-compounds touched upon in the book. Of these sketches a considerable number are of different pieces of chemical apparatus made use of in testing the raw or finished material.

The author first briefly considers some of the chemical groups from which the nitro-compounds are formed, and, in doing so, volunteers the statement that "the nitro-explosives belong to the so-called High Explosives." This, however, depends very much on whether these explosives are intended to be used as disruptive agents for producing local effect, or as propelling agents. In other words, taking Hess's definition, a high explosive is one which requires the use of a detonator to develop its full value, as with guncotton or dynamite; a low explosive, as gunpowder, does not require a detonator, but will exert its full power by simple ignition. Here again, however, we require to make some qualification as, although all the nitro-explosives are high explosives in one sense, it depends on whether they can, or cannot, be detonated in order that we may define them as high explosives pure and simple, or as explosives of high energy. Practically speaking, only the latter are suitable for propelling or ballistic purposes, while the former class should be used as blasting agents only. An explosive which can be detonated by a detonator, can also, by suitably confining it, be often exploded by a simple ignition in such a manner that its explosion really becomes a detonation, or partakes of the nature of a detonation, *i.e.* very high local pressures are developed. It is, therefore, a matter of considerable importance to definitely ascertain that explosives to be used as ballistic agents cannot be detonated.

The chief value of the book depends on those portions dealing with the manufacture of nitro-glycerine, dynamite, and guncotton, and the testing of the raw and finished material. The descriptions relating to these explosives show very evidently that the author has personally participated in their manufacture, and his remarks, which are generally to the point, are consequently of considerable value to chemists and others engaged in similar operations. Mr. Sanford very properly lays much stress on the testing of the materials used in all the stages of manufacture, and it will be found that nearly as much space has been devoted, in different parts of the book, to testing and analysis as to the actual manufacture of the explosives. Unfortunately, the reader is credited with being already more or less familiar with the appliances connected with the manufacture of explosives, and therefore the author apparently considers that a brief notice is all that is necessary. Nitro-glycerine and nitro-cellulose have, however, become so important in connection with civil and military undertakings, that those who employ such explosives are glad to be able to read an interesting account which is trustworthy without being exhaustive, and which does not make too great a demand on the pocket. To such this book is especially recommended, as these substances receive the greatest share of attention, and they form the basis of the more powerful and popular blasting materials, and also of practically all the smokeless powders used in small arms or artillery; but, besides these uses, nitro-cellulose (collodion-cotton) is employed to a very large extent in the production of that most useful material called celluloid, xylonite, or imitation ivory, of which so many articles of every-day life are made, such as knife-handles, buttons, photographic dishes, and billiard balls. The manufacture of this substance forms one of the most interesting portions of the book, and, although not properly coming under the category of an explosive, it finds a fitting place in this work.

It must not, however, be forgotten by those who make use of celluloid that it becomes, under certain conditions, a powerful explosive. Celluloid shavings also should never be allowed to accumulate, as they take fire easily at a comparatively low temperature, and, in this state, burn with surprising rapidity.

In the analysis and testing of explosives, to which, as we have stated above, due prominence has been given, the various operations are briefly but concisely explained. They are evidently written for the use of practical chemists, and will, no doubt, be duly appreciated by them. With regard to the heat or stability test which is applied to most explosives before they are passed for service, it has lately been put beyond doubt that the sun's rays have a marked effect on some explosive substances,

thereby shortening very materially the length of time they are able to stand the test, without, however, undergoing any other suspicious change; indeed, if they be subsequently allowed to stand for a time in a cool place out of the reach of white light, they recover their apparently lost property, and stand the heat test as well as ever.

The effect of sunlight on both guncotton and nitroglycerine has long been known, but it is only lately that this important point has received much consideration in Government and private factories. Care is now taken to screen off direct sunlight, or even white light, by some non-actinic material placed over the windows.

We feel constrained to make a few remarks on one other point, viz. the author, in detailing the various advantages claimed for a certain smokeless powder, states that it gives *lessened recoil* and *high velocity*. Now these are very common advertising phrases of no practical value, as the recoil of a gun is nearly proportional to the velocity of the projectile, by a well-known law of dynamics. Taking the figures given—38 grains of the particular powder referred to was necessary to obtain the same velocity (about 2000 f.s.) as the service charge of cordite, 31 grains in the Lee-Metford rifle with a 215 grain bullet. Now

$$\text{Velocity of recoil} \times \text{weight of gun}$$
$$= \text{velocity of bullet} \times (\text{weight of bullet} + m \text{ weight of charge}),$$

m being a factor, which is found by experiment to be practically constant.

It will be seen at once that, other conditions being equal, the heavier charge must give the greatest recoil.

H.

THE PRACTICE OF MASSAGE.

The Practice of Massage; its Physiological Effects and Therapeutic Uses. By A. Symons Eccles, M.B. Aberd. Pp. 377. (London: Macmillan and Co., 1895.)

THE rubbing and kneading of the surface of the body, and various modifications of such processes for the relief of pain, have been in vogue from time immemorial in many countries, both civilised and uncivilised. It is well known, indeed, that the natives of India have always largely employed such measures, and that even among the aboriginal tribes of America something of the kind has been practised. Mechanical frictions and rubbings were included by Hippocrates and Galen in their systems of therapeutics, and in some form or shape they have ever since been in use in the older spas and baths of Europe. But although the practice is so ancient and so widespread, its admission into modern medicine as a recognised means of treating disease only dates from the present century, and the literature of the subject—now comparatively large—may be said to have had little or no existence fifty years ago. The Scotch and French physicians seem to have been the first in modern times to investigate the subject scientifically; and it is to the latter, in particular, that we owe the systematic ways of application of the various manipulations now in use, as well as the nomenclature which is now practically universally adopted by practitioners in all civilised countries. Within the last few decades a considerable number of valuable observations on the uses and effects of massage have been published, as well as several comprehensive text-books on the subject. Among these latter, the work now before us is likely to take an important position; for not only is it the outcome of a lengthy and extensive practical experience on the part of the author, but it is written in a scientific spirit, and, indeed, constitutes a very able *résumé* of the whole subject.

Dr. Eccles commences by describing the different manipulations and the methods of applying massage in general, as well as to particular parts of the body. In the second chapter, he treats of the physiological effects of massage; and it is in this department that we naturally feel most interest. As might be expected, the effects vary with the kind of manipulation; thus gentle "effleurage," or skin stroking, will give rise, first, to a pilo-motor reflex, or condition of "goose-skin," and if firmer friction be employed, a dilatation of the superficial cutaneous vessels is produced, followed by increased activity of the sweat glands. The direction of the stroking being centripetal, the contents of the superficial veins and lymphatics are forced along, and the rapidity of the cutaneous circulation increased. Among the important results of effleurage, the author mentions a general soothing effect on the nervous system, and an acceleration of the heart-beat. With the process of "pétrissage," or the kneading, rolling, and squeezing of the integuments and underlying tissues, it is shown that the circulation of the skin and contiguous muscles is still more accelerated, the absorption of waste products promoted, and the general nutrition of the parts improved. Muscle-kneading thus serves as a substitute for muscular exercise, and also as a restorative of fatigued muscle. The experiments of Lauder Brunton and Tunnicliffe on the effects of massage on blood-pressure are here alluded to, as well as the author's interesting observations on the results of muscle-kneading on the temperature of the body.

"Tapotement," or the delivery of a rapid succession of blows, produces its principal effect through the direct stimulation of the nerve trunks; localised muscular contractions are induced; and if applied over a molar nerve, the muscles supplied by that nerve are profoundly affected. The author observes, moreover, that stimulation of the sensory nerves by this "muscle-hacking" while producing increased temperature and vascularisation of the part so treated, may also give rise to symmetrical reflex secretion. The various movements classed under the head of "vibrations," are also designed to act mechanically on the subjacent nerves, and thereby to produce reflex effects of a sedative character. The author has frequently, for instance, observed relief following nerve-vibration in non-inflammatory abdominal pain. The so-called "massage à friction," especially used for the manipulation of joints, is a combination of rubbing and kneading, having for its purpose the dissipation and squeezing out of waste products from the tissues in which they have accumulated; and in this connection von Mosengeil's experiments are quoted, which show conclusively that artificial injections in a joint can be removed by massage, and forced into the ascending lymphatics.

The succeeding chapters of the book treat of the

therapeutical uses of massage in affections of the skin, of the muscles, in rheumatism, sprains, dislocations and fractures, disorders of digestion, anæmia, obesity, nervous affections, insomnia, heart diseases, and in many other maladies in which mechanical manipulations, intelligently and skilfully employed, have been proved to be efficacious after other means of treatment have failed.

The author gives, throughout his work, succinct and practical directions, which will prove of the greatest use to those practitioners who have had no experience of a treatment which is now generally accepted in the medical profession as one of the most useful in therapeutics.

OUR BOOK SHELF.

Catalogue of the Fossil Bryozoa in the Department of Geology, British Museum (Natural History). The Jurassic Bryozoa. By J. W. Gregory, D.Sc., F.G.S., F.Z.S. Pp. 239; pl. xi. (London: 1896.)

THIS catalogue is a valuable addition to the twenty-two monographs which have already been devoted to the various groups of fossils preserved in the Geological Department of the Natural History Museum. The Trustees of the British Museum have earned the gratitude of palæontologists, and of naturalists generally, by bringing together such a wealth of information upon the fine collections under Dr. Henry Woodward's care.

In an introduction, Dr. Gregory discusses the problem of tubular fossils, the affinities, and the structure of Bryozoa, the terminology of the shells of the Cyclostomata and Trepostomata, and the value of generic divisions in the latter order. In this section, the differences of opinion between those who attribute generic value to trivial differences, and those who prefer to restrict the number of genera, are described. The discussion of transitions traced in groups of Cyclostomata, leads to the examination of the question whether there are really genera and species among Cyclostomatous Bryozoa. Taking the genera *Diastopora* and *Berenicea* as exemplifying the real value of zoarial characters in the order, they seem to support the admission that "there are no true genera among Cyclostomata, but only certain convenient, but artificial, groups of species. . . . I therefore accept the terms *Stomatopora*, *Proboscina*, &c., as names for convenient groups, which are not altogether artificial, but which are not genera in the sense in which that term can be used among Echinoidea and Mammals. They could be better described as circuli than as genera."

From the subject of generic divisions, Dr. Gregory passes to specific groups and individual variations. The comparison of the forms of Bryozoa that lived in successive geological periods, appear not to lend support to Mr. Bateson's views as to discontinuous variation. "The general evidence of the fossil specimens," says Dr. Gregory, "and the great difference of opinion as to the range of specific variation between those who multiply species indefinitely, and those who place Silurian and recent individuals in the same species—tend to show that most of the forms of Cyclostomata have arisen by slow, imperceptible, continuous variation."

With the exception of two species (both members of the order Cheilostomata), all the Jurassic Bryozoa belong to the order Cyclostomata. This order is classified by Dr. Gregory into four sub-orders, viz.: I. Articulata; II. Tubulata; III. Dactylethrata; IV. Cancellata. The first of these groups is not represented in the Jurassic, and species of the fourth group do not appear until the Cretaceous period. The names of the second, third, and fourth groups are based upon zooecial structure, while the subdivisions of the groups depend upon zoarial characters.

From the foregoing outline of the teachings of Dr. Gregory's examination of the Bryozoa of Jurassic times, it will be concluded that the catalogue furnishes facts of distinct value in working out the evolution of the class. Eleven plates, containing many admirable drawings of the species described, have been prepared for the catalogue by Miss G. M. Woodward. These, with the careful determinations and critical introduction, make the catalogue not only most acceptable to all palæontologists, but also of the greatest interest to systematic zoologists.

Water Supply (considered principally from a Sanitary Standpoint). By Wm. P. Mason. Pp. 504. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

THIS is an unusually interesting treatise on a technical subject, about which so much has been already written, and the author is to be congratulated on the large amount of new information which he has succeeded in compressing into a comparatively small volume without rendering it heavy and unreadable. The book is full of facts gathered from the most varied sources, so that even the expert in this department of knowledge will find it a convenient work of reference, whilst it may also be perused with great profit by that large and ever-increasing body of laymen who, as medical men, members of local boards, landlords, and the like, are supposed to have some acquaintance with this subject, and whose responsibilities in this connection are generally out of all proportion to their knowledge. Prof. Mason has collected the results of the principal investigations bearing on the sanitary aspects of water supply, made both in Europe and America, and European readers should be specially grateful to him for the lucid and concise manner in which he has summarised and abstracted the important trans-atlantic labours in this direction, and the original description of which is only to be found in comparatively inaccessible and exceptionally voluminous writings of an official character. There are many points in connection with the sanitary aspects of water supply, on which, as is well known, the most conflicting opinions are prevalent amongst experts, and not the least commendable feature in this work is the impartiality and fairness with which the author has marshalled and reviewed the evidence adduced by the contending parties.

Botany for Beginners. By Henry Edmonds, B.Sc. Pp. 117. (Longmans, Green, and Co., 1896.)

THE author hopes that this little botany primer "may be the means of exciting an interest in the subject in the minds of the young." He is a teacher, and should therefore know that a multitude of new names is the reverse of exciting to young students, yet this is how the definitions are crowded in on page 3: "They [certain leaves] are spoken of as **radical** leaves (Latin, *radix*, a root). Others are attached to the stem, and are described as **cauline** (Latin, *caulis*, a stem). The radical and lower cauline leaves possess a stalk, or, as it is called, a **petiole.** This attaches the flattened part, or **blade**, to the stem. The upper cauline leaves have no such stalk, the blade being immediately attached to the stem, or **sessile.**" And again on page 5: "Each of these is called a **carpel**, while the group of carpels is termed the **pistil.** Each carpel consists of a swollen portion, the **ovary**; on top of this there is a little head. the **stigma.**" This is all very well, and the language of botany must, of course, be learned at some stage or other; but, at the same time, the designations follow one another so closely, that the pupils who use the volume as a reading-book will get bewildered.

The book is not, however, without its good points. It is liberally illustrated, the descriptions refer to common British flowers, and a few simple experiments are introduced to exemplify the functions of the different organs of plants. A good teacher may make the lessons in the book interesting, but of themselves they are not very inspiring.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Utility of Specific Characters.

PROF. LANKESTER'S lucid statement in NATURE for August 20, shows that a part of his objection to my position is due to my own want of skill in stating clearly what I mean.

I am far from wishing to reject the method of imaginative hypothesis and subsequent experiment or observation. I respect that method as sincerely as Prof. Lankester himself, and although I cannot pretend to his measure of skill in using it, yet, so far as I can see, I have, in my work on the frontal breadth of crabs, employed this very method to the best of my ability. The hypothesis with which I started was, that if natural selection acted upon the frontal breadth of crabs at all, there ought to be a demonstrable difference between the percentage of abnormal frontal breadth in young crabs, and the percentage of the same abnormalities in older crabs; and I proceeded to test this hypothesis by measurement of crabs of different sizes. The result showed that a change in the frequency of abnormal frontal breadth could, in fact, be observed. The effort of imagination was here small enough, but, such as it was, it served to guide my first step; and, having made this first step, I had to formulate a second hypothesis. A diminution in the frequency of abnormal frontal breadth, with increasing size of crabs, might be due either to a selective destruction of abnormal crabs during growth, or to a modification of these crabs, by which abnormal individuals lose their abnormality as they grow. In order to decide which of these imaginative hypotheses should be adopted, I have spent a great part of the last two years in ascertaining the law of growth of crabs, so far as their frontal breadth is concerned. Setting the question of skill on one side, the only difference I can perceive between the method of this whole investigation and that of any research conducted by Prof. Lankester, is a difference in the tools employed in verification of hypotheses. The only tool which I have used has been some kind of measuring scale; and, although this kind of tool is more unpleasant to work with than those used by more fortunate persons, it does not imply any difference in the method of work.

Further, assuming the law of growth to yield evidence of selective destruction, so that change in frontal breadth is correlated with change in death-rate, I heartily agree with Prof. Lankester that a further hypothesis ought to be formulated as to the whole process connecting change in frontal breadth (and the whole group of characters correlated with it) with change in death-rate. The only step taken by Prof. Lankester, which I cannot follow, is the admission of hypotheses in which some of the factors of the problem are neglected. I should like to explain what I mean by this.

In *Carcinus mænas* I have shown that change of frontal breadth is correlated with change in several other dimensions of the exoskeleton; and I have no doubt that it is correlated also with change in the size and shape of several internal organs, such as the brain, liver, kidneys, and others. I have not measured such an oxyrhynchous crab as *Stenorhynchus*; but it is probable that the changes among internal organs correlated with change in frontal breadth, will prove to be very different in such a crab as *Stenorhynchus* from the corresponding changes in *Carcinus*.

Let us suppose, therefore, that the liver is shown to vary when the frontal breadth of *Carcinus* varies, but not when the frontal breadth of *Stenorhynchus* varies; and suppose, further, that an hypothesis is submitted as to the process by which change in the liver of *Carcinus* leads to change in the death-rate. It seems to me that, unless one of the steps in this process involves a change in frontal breadth, the hypothesis must be rejected, because one of the properties of the liver of *Carcinus* is not accounted for. The hypothesis submitted may be true of *Stenorhynchus*: but, since it neglects one of the differences between that animal and *Carcinus*, it cannot be true of both.

To put the matter in another form: suppose I wish to obtain hydrogen from sulphuric acid, I can do so by adding to the sulphuric acid a certain quantity of zinc. From a known quantity of sulphuric acid I can obtain a definite quantity of hydrogen, and I shall, in so doing, dissolve a definite quantity of zinc with the formation of a definite quantity of zinc sulphate. If, instead of dissolving zinc, I dissolve iron in my sulphuric acid, I can still obtain from it the same quantity of hydrogen, but the quantity of iron required will not be the same as the quantity of zinc used in the previous experiment, and the resulting sulphate will be different. It is, of course, impossible to form an exact hypothesis of what occurs in either of these cases, if I pay attention only to the evolution of hydrogen, and regard the formation of sulphate as an unimportant concomitant. I must in each case form a theory of the behaviour of the metal, the hydrogen, and the acid radicle; and, so far as it fails to account for any fact concerning any one of these bodies, my theory is imperfect.

In precisely the same way, it seems to me that we ought not to rest content with any theory of an animal structure which does not account for all the phenomena associated with it; so that a theory of the function of frontal breadth in a crab should, I think, involve every organ correlated with it. It may be said that such a theory is unattainable because of its complexity; and this is certainly at present true; but the habit of regarding one or other of the properties of an organ as unimportant, would for ever prevent the formation of such a theory even if it were otherwise possible.

It is this sense of the necessary complication of such hypotheses which makes me glad to assert that they are unnecessary to a knowledge of the factors of evolution. It is possible to know that change in frontal breadth in a *Carcinus*, for example, is associated with change in death-rate under the conditions of Plymouth Sound; so that those crabs in which the frontal breadth has a particular magnitude, can be known to have a greater chance of living and breeding than those of different frontal breadth. A complete knowledge of the processes associated with this relation between frontal breadth and death-rate is a thing of very great interest, and I believe, as firmly as Prof. Lankester, that every effort should be made to attain to it; but, desirable as it is, it is still not necessary in order to know that a crab's chance of living and breeding may be known by measuring its frontal breadth. It is not necessary in order that the change in mean frontal breadth may be measured from generation to generation, and the direction and rate of evolution by this means ascertained. W. F. R. WELDON.

Marine Biological Laboratory, Plymouth, August 26.

The Death of Lilienthal.

I HAVE received this authentic report of Mr. O. Lilienthal's death. If you think the letter worth publishing in NATURE, it is at your service. C. RUNGE.

Hannover, Technische Hochschule.

YOU are right in presuming that I can give you details referring to Otto Lilienthal's death, authentic as far as they can be obtained.

As early as the beginning of last spring, Lilienthal's experiments had taken a new departure. He had gradually come to the conclusion that the surfaces employed by him were not sufficient.

With a surface of twelve to fourteen square metres he could take sufficiently long flights to serve his purpose of observation and practice in strong, gusty wind, but he very rightly considered experimenting in a strong wind to be too dangerous, and with a light breeze about twenty square metres were found necessary. This enormous surface, however, could not be handled with the same certainty and exactness as the older wings, and as his system of steering consisted in shifting his weight within the surface upon which it was suspended, he had hit upon the simple expedient of placing two surfaces one above the other.

This system promised from the beginning to be a very marked advance. In former days Lilienthal had tried, over and over again, to make small paper models that would soar like birds, and had always been disappointed. Now this problem seemed to be solved. These two-story models, which resembled beetles rather than birds, soared in the most astonishing manner. He would let them off from the top of the artificial cone which he had erected at Lichterfelde, and they would take long and sometimes circuitous flights into the surrounding fields, and never showed the slightest tendency to take "headers"—a peculiarity very frequently hitherto observed in soaring models.

These experiments, therefore, seemed to prove that not only would a two-story surface be more easily steered, because a

definite shifting of the centre of gravity to one side would have a more marked effect (since the lateral extension of the whole structure was little more than half of that formerly used), but would also show a greater stability, a result all the more to be expected, as the centre of gravity of the system was placed more than a metre below the upper surface.

Experiments, which were begun without loss of time, seemed to bear out this conclusion. Lilienthal appeared to have suddenly gained in power and in the faculty of shaping his motion at will. It seemed to be only a question of time or opportunity that the great step would succeed of describing a complete circle in the air (which always appeared to us to be the key to a definite, if not complete success), when the disastrous accident occurred which has cost the bold experimenter his life.

The following is, as nearly as I can remember it, the report of the mechanic who used to build Lilienthal's wings, and to help him with his experiments.

On Sunday, August 9, Lilienthal had gone out to the village Rhinow, where he used to practise on the bare sand-hills in the neighbourhood. Nobody was with him except his mechanic. The weather was exceptionally favourable, a light wind blowing from the east with a velocity of about 5—6 m. per second.

Lilienthal had selected one of these new two-story surfaces, which, in a considerable number of trials from the artificial cone in Lichterfelde, had shown itself to be especially successful. He took one flight, by way of warming to his work, and then prepared himself for a second, and gave the word to his man to look at his watch and note the duration of the flight. The man saw him soar down until he was nearly above the foot of the hill, then suddenly a gust of wind set in, lifted him up to a height of 30 m. above the ground—according to his man's estimate—and there he stood apparently motionless in the air.

This was a frequent occurrence, and gave no cause for alarm at first; but now the man saw how Lilienthal gradually lowered the fore-edge of his wings more and more, without obtaining the desired effect of getting way forward and downward. The man felt uneasy at this, pocketed his watch, and began to run towards the spot where his master was hanging suspended in mid-air. Suddenly he saw the apparatus heeling over forward still more, and then Lilienthal came down with it with great force head foremost, rolled over once or twice after striking the ground, and remained motionless.

When the man reached the spot, he found the apparatus much shattered, but Mr. Lilienthal apparently uninjured though without consciousness. The local physician was instantly summoned, and at first declared that nothing serious had happened. Lilienthal was brought to the neighbouring inn, and within two hours recovered his senses. He seems to have felt no pain, because he immediately declared he would soon get up and continue practising. However, his arms and legs were lamed. It appears that his spine was fractured.

The man left him to the care of the physician, and took the next train to town to fetch his brother. When the brother came, he found that he had swooned again; and he did not recover his consciousness until death set in, which occurred the same night.

By publishing these lines the editor of NATURE will, I think, fulfil a duty he owes the scientific world, as well as the memory of a man who, throughout his toilsome life, applied his rare energy, courage, and ability to the solving of a problem which has hitherto baffled the ingenuity of all modern engineering.

Lilienthal, who was a successful engineer and manufacturer, has not lived to see his forty-eighth birthday. He leaves a widow and three children.

A. DU BOIS-REYMOND.

Berlin, August 24.

Laboratory Use of Acetylene.

NOW that acetylene has come so much into prominence, an instance of its use in a laboratory which possesses no gas supply may be an encouragement to any one similarly situated. Long doomed to the use of spirit-lamps, "benzoline roarers," and the like, the cheap production of acetylene has come as a great boon to us, and is now in regular use for blow-pipe work. The apparatus in use consists of an aspirator holding about fifteen litres, permanently connected with a water supply, and possessing a ¼-inch aperture exit tap (the water flows in from below to minimise absorption); at the top a three-hole rubber cork carries an upright pipe passing through the table, which serves for filling the aspirator with gas, or using the gas on the table, a second pipe goes to the blow-pipe, and a third carries an open mercury manometer. For filling the jar, the calcium carbide is placed in a four-ounce bottle closed by a cork carrying a small separating funnel from which the water drops; the gas passes to the aspirator through a wide glass tube which acts as a reversed condenser, returning most of the water vapour to the bottle. With the large exit to the aspirator the gas can always be collected under a reduced pressure of several cms. of mercury, which quite provides against any sudden rushes of gas; the operation takes some ten minutes, and requires practically no attention.

In using the gas the water is turned on with all taps closed for a few seconds, to correct any reduced pressure caused by absorption, as shown by the gauge (this is very slight indeed), and then the gas-tap fully opened and the flame regulated entirely by the water entrance. To bring the gas into use takes hardly any longer than with an ordinary gas blow-pipe. A good fusion on platinum foil (*e.g.* $BaSO_4 + Na_2CO_3$) may be effected by using about one litre of the gas. We have used the apparatus for about two months, and I recently discovered that some of my junior workers did not know what acetylene smelt like, which speaks well for it if not for them. I am hoping to introduce the gas on to the benches if the difficulty of the enormous quantity of air required to produce a non-luminous flame can be overcome.

The Laboratory, Felsted School.

Coal-dust.—A Question of Priority.

IN the report of a lecture given *in extenso* at page 64, *et seq.*, in the *Colliery Guardian*, for July 10, on "Coal-dust and Explosives," by Mr. H. Richardson Hewitt, of Derby, H.M. Inspector of Mines, the following remarkable statements occur:—

"It was but a few years ago that the Messrs. Atkinson first drew attention to their idea that coal-dust was a dangerous element in mines where blasting operations were carried on . . ."

"After Messrs. Atkinson first drew attention to the subject, Prof. Galloway took it up and made some rough experiments by placing gunpowder cartridges in heaps of coal-dust and firing them in the dark."

Although these statements were obviously uttered in ignorance of the nature of my experiments, they raise a distinct and palpable issue as to priority.

The facts are as follows:—

My first experiments with coal-dust were made on July 3, 1875. I then discovered that a mixture of air and fire-damp, which is not inflammable at ordinary pressure and temperature, on account of the smallness of the proportion of fire-damp present in it, becomes inflammable when coal-dust is added to it, and can be ignited by means of a comparatively small flame.

On December 22, 1875, I gave evidence in the capacity of Assistant Inspector of Mines at the Coroner's inquest on Llan Colliery Explosion (South Wales District), when I attributed that explosion principally to the influence of coal-dust. My evidence was discountenanced by the Chief Inspector of Mines for the district, and was not embodied in the Reports of the Inspectors of Mines, but it was reported *verbatim* in the two local newspapers (*Western Mail* and *South Wales Daily News*) of December 23, 1875.

On March 2, 1876, I read my first paper, entitled "On the Influence of Coal-dust in Colliery Explosions," before the Royal Society. In that paper I announced the coal-dust theory.

In 1878 I published a large number of articles in *Iron*, under the title of "Coal-dust Explosions." In these articles, amongst many other things, I quoted and commented upon what Faraday and Lyell had written about coal-dust upwards of twenty years previously, and I gave complete translations of the papers that had been published in France, having a bearing upon the subject.

Besides contributing a number of other articles and papers on the same subject to various societies and periodicals, I read altogether five papers "On the Influence of Coal-dust in Colliery Explosions" before the Royal Society, viz.: March 2, 1876, already referred to; February 27, 1879; May 30, 1881;

December 29, 1881; May 8, 1884; and one on "A Coal-dust Explosion," February 17, 1887.

During the ten years ending in 1885, I was engaged from time to time in carrying out experiments with coal-dust: first, with apparatus provided by the Glamorgan Coal Company, Limited, and erected at their Llwynypia Colliery; secondly, with apparatus purchased by means of Government grants obtained through the Royal Society; and, thirdly, with apparatus belonging to the Royal Commission on Accidents in Mines.

Before the accounts of my earlier investigations, and the conclusions founded upon them had appeared, the Inspectors of Mines and other mining experts were practically unanimous in attributing the cause of every great colliery explosion to the sudden outburst of a large volume of fire-damp which was supposed to have flooded the workings, become mixed with the air, and, on being ignited in one way or another, produced the various phenomena subsequently observed. This explanation was accepted everywhere as the only one possible; it was recorded in the official reports of the Inspectors of Mines, and they, as well as the experts of that generation, were irretrievably committed to it.

There was not, figuratively speaking, a ripple of dissent from this mode of explanation upon the placid surface of mining opinion at the moment the coal-dust theory was launched upon it.

At first the new theory was ignored; then it was scouted; then it was subjected to scathing criticism; then it was taken up in a tentative manner by some of the younger and bolder men: and, lastly, when it was found to be making serious headway, one of the more adventurous spirits suddenly discovered that it was not new after all, for had not Faraday and Lyell and certain French engineers been its real authors?

Following my lead, first a joint paper, by Messrs. Hall and Clark, was contributed to the North of England Institute, in May 1876, then another by Messrs. Marrecco and Morrison, in 1878, all of whom, with the exception of Mr. Clark, had previously corresponded with me on the subject of explosions; finally, in the year 1879, after the publication of my articles on "Coal-dust Explosions" in *Iron*, and during the next few years afterwards, a very great army of investigators, headed by Government Commissions in England, France, Prussia, Austria and Saxony, and including the Messrs. Atkinson, entered the field.

Some of these investigators contented themselves with criticism pure and simple; others, of whom many had neither aptitude nor training for the work, made experiments with small and imperfect apparatus, and, as a consequence, obtained only negative results; still others were carried away by the side issues; and only a few, such as the Prussian and Austrian Commissions, and Messrs. Hall and Atkinson, H.M. Inspectors of Mines, did really good and substantial work of an enduring kind.

The facts and conclusions recorded in my earlier papers were freely drawn upon: by some they were generously acknowledged; by others they were first denounced and then assimilated; by others they were adopted without acknowledgment; while some of my experiments, and notably my investigations into the nature of the Fire-damp Cap (*Proc. Roy. Soc.*, March 2, 1876), were repeated with some variations and described as if they were original.

A flood of literature was now poured upon the mining world from every side, embodying opinions of the most conflicting and mystifying character, such as—a mixture of coal-dust and air may take fire but it cannot explode; coal-dust can only carry flame from one accumulation of fire-damp to another; a coal-dust flame cannot extend throughout the workings of a mine in the entire absence of fire-damp; a small proportion of fire-damp must always be present in the air when an explosion takes place; some kinds of coal-dust are more inflammable than others—and so on, so that amid the din and hurlyburly of the strife the main question of how to put an end to great explosions was almost lost sight of.

But the scene of each successive explosion when viewed under the new light served gradually to dispel the illusions which had fascinated the majority of the investigators for years; and thus it has come to pass that the new generation of Inspectors of Mines, and those who have been associated with them in investigating the phenomena of explosions, have become convinced, I believe almost to a man, of the soundness of the coal-dust theory; and that the struggle of contending factions, which was at its height ten or twelve years ago, has gradually subsided, leaving us face to face with a work which still remains to be done, namely, to render the occurrence of a great colliery explosion impossible in the future.

Into the consideration of that problem I do not propose to enter on the present occasion, as I have lately done so in considerable detail in the pages of the *Daily Chronicle* of June 24 of the present year.

W. GALLOWAY.

Cardiff, July 17.

THE AUGUST METEOR SHOWER, 1896.

THE moon being absent from the nocturnal sky during the recent return of the Perseids, encouraged the hope that the shower would be somewhat brilliant; but the weather is an element of great importance in such observations, and it was by no means favourable during the late display. In the south of England several nights were partly clear near the important time, and on August 10 the firmament at Bristol was almost free from dark cloud; but the sky was hazy and the stars dim, so that only the brighter meteors were observed.

On August 6, during an hour's watch before 10h. 50m., I counted twelve meteors, of which seven were Perseids, with a radiant at $42° + 56°$. The shower was evidently pretty active, and the meteors fairly bright, but clouds overspread the sky before 11h., and prevented further observation.

On August 7, in an hour's watch preceding 11h., nine meteors were seen, including about six Perseids, but clouds were very prevalent during the whole time, and effectually obliterated the stars at a later period of the night.

On August 10 the weather was fine, but the atmosphere was not transparent enough to be considered favourable for meteoric work. Haze was spread over the sky, and the fainter stars were obscured. Near the horizon nothing could be discerned. I began watching for meteors at about 9h. 50m. and continued until 14h. 15m. During this interval of 4h. 25m. I saw ninety-eight shooting-stars, of which sixty-nine were Perseids, and twenty-nine belonged to the minor, contemporary showers of the period. I registered the apparent paths of a considerable number of the meteors seen, and while engaged in doing this, must have missed many others which appeared while my attention was diverted from the sky. It is probable that fully one hundred and fifty meteors would have been counted by an observer watching the sky uninterruptedly during the period mentioned. Nearly all the Perseids left streaks, but the meteors generally were not very bright. The radiant point was tolerably well defined, but it was certainly not so definitely marked as I have sometimes seen it. I determined it at different times of the night as follows:—

h. m. h. m.		° °
9 50 to 11 0	... ...	43 + 57
11 0 to 11 30	... ...	44 + 57
11 30 to 13 0	... ...	46 + 57
13 0 to 13 45	... ...	45 + 59
13 45 to 14 15	. ...	46 + 57

The mean of the five positions being at $45° + 57°$, which coincides with the usual place of the radiant on August 10.

On August 11 the heavens were overcast, but on August 12 a beautifully clear sky enabled me to resume observations. I saw fourteen meteors in about an hour and a quarter before 11h. 15m., and of these seven belonged to the Perseid shower. The radiant was at $46° + 57°$, but it was imperfectly defined.

On August 14 the firmament was again clear, and I saw nine meteors in three-quarters of an hour before

11h. 10m., of which one only was a Perseid. The shower had evidently become nearly exhausted.

The following conspicuous meteors were recorded on the several nights of observation, and I give their paths in the hope that they have been observed elsewhere.

1896.	Time.	Mag.	Path From	Path To	Length.	Radiant.
			° °	° °	°	° °
Aug. 4	9 46	1	343 +31	335 +10	27	42+56
6	10 6	2	340 +31	337 +58	27	342−12
6	10 6	1	343 +32	328 +10	26	42+56
10	9 54	1	103 +86	202 +79	13	43+57
10	10 39	2	27 +48	355 +39	24	60+48
10	11 24	1	15 +47	9 +43	6	44+57
10	11 39	♃	66 +84	210 +81	15	46+57
10	12 6	2	42 +45	44 +39½	6	28+72
10	12 10	2	44½+35	53½+31½	8	23+40
10	12 15	> 1	28 +24	24 + 4	20	46+57
10	12 19	2	60½+31½	66 +26½	7	47+42
10	12 46	1	8 +12½	1 − 3	17	46+57
10	13 8	♃.	633 +63	25 +66	5	45+59
10	13 19	1	23½+20	20½+12½	8	45+59
10	13 22	1	359 +69½	334 +68	9½	45+59
10	14 14	> 1	57 +76	225 +77	27	51+31
12	9 24	♃	195 +24	199 + 9	15	46+57
12	10 41	2	26 +43½	30 +38	6	331+70
14	9 24	1	265 +22	240½+19	23	356+ 5

On the whole, I regard the display as one much inferior to many observed in past years. Both as regards the number and brilliancy of the meteors there was nothing striking to record. Had the sky proved clearer on August 10, many small meteors would have been visible, which, under the conditions prevailing, were enabled to escape detection; but making every allowance for this, there is no doubt the shower was not a conspicuous one.

As to the displacement of the radiant, which takes place on successive nights, this was indicated from my results on August 6, which gave $42° + 56°$ for the position, while on August 10 it was $45° + 57°$, and on August 12, $46° + 57°$. But my observations this year have not been sufficiently extensive for the full and proper re-investigation of this feature, nor is it required, for no good end is served by the frequent re-observation of a fact already well determined.

The usual minor showers were visible; indeed, there appears to be very little doubt that the great majority of meteor radiants are manifested annually without any great change in their visible strength. Certain showers vary more than others, but many of the differences observed are due to the alteration in the conditions under which they are presented from year to year. In 1893 there was a strong shower of Cygnids observed contemporaneously with the Perseids, but the former was but slightly seen this year, for I recorded only two of its meteors. I registered meteors from radiants at $31° + 20°$, $28° + 72°$, $60° + 48°$, $331° + 70°$, $356° + 5°$, which have been noticed in preceding years, and are among the best assured positions of the August epoch. Feeble showers of this character are extremely numerous, and require long watches before an observer can satisfactorily determine their radiants. Some of them fall so near together that they cannot be disassociated unless the observations are very numerous and accurate.

I observed no fireballs during the recent return of Perseids; but Mr. Blakeley, of Dewsbury, reports that he saw meteors as brilliant as Venus on August 10, at 11.40 and 12.16, both Perseids.

The Rev. S. J. Johnson, of Bridport, writes me that he observed a good many bright meteors this year. One of the finest appeared on August 10, 9h. 50m., travelling from ϵ Cassiopeiæ to a point 7° west of β in the same constellation. Two second magnitude meteors were seen within fifteen seconds of each other at about 10h. 6½m. on the same night, which were also observed at Bristol. Their heights at beginning were 64 and 65 miles, and at ending 46 and 52 miles respectively. They were both Perseids.

Mr. Blakeley, of Dewsbury, saw about thirty-five Perseids between 11h. and 12h. 30m. on August 10, and the paths seemed to give a sharply-defined radiant at the usual maximum position.

Mr. S. H. R. Salmon, of Croydon, saw, on August 10, 20 meteors (15 Perseids) between 9h. 10m. and 10h., and 18 meteors (16 Perseids) between 10h. 10m. and 11h. The sky was perfectly clear.

Mr. D. Booth, of Leeds, on August 11, saw eighteen meteors in the forty-five minutes from 10h. to 10h. 45m., and found the Perseid radiant at $47\frac{1}{2}° + 58\frac{1}{2}°$.

W. F. DENNING.

THE LIVERPOOL MEETING OF THE BRITISH ASSOCIATION.

III.

IT is possible now to forecast to some considerable extent the work of the various Sections from the information already received from presidents, recorders, and authors.

In Section A (Physics), Prof. J. J. Thomson's opening address will deal, we believe, with (1) the teaching of physics; (2) the kathode and Röntgen rays; (3) the passage of electricity through a gas; and (4) the movement of the ether. Friday will be devoted in this Section chiefly to phenomena connected with the Röntgen rays; and on Saturday the Section will divide into the two departments of mathematical physics and meteorology.

In Section B (Chemistry) the address of the President (Dr. Ludwig Mond) will deal with the development of the industrial manufacture of chlorine. Technical papers will probably occupy a large portion of Friday's sitting, including a report, by Prof. Bedson, on the composition of coal. On Monday, Prof. Ramsay will read a paper on helium, and there will be a number of other communications on helium and argon. On the same day, a paper will be read on the synthesis of the elements. It is hoped that this will lead to a discussion, to which several have promised to contribute. Other matters of interest will be an exhibition of photographs of explosions in various gaseous mixtures, by Prof. Dixon, and the report of the Committee on science teaching in elementary schools, which will be followed by a paper on science teaching in girls' schools, from Miss Walters.

It is hoped that the numerous chemical works in the neighbourhood may prove attractive to the members of the Section, and arrangements are being made for members of the Section to visit several of the most interesting works on special afternoons.

Mr. Marr's address to Section C (Geology) will be devoted to recent advance in stratigraphical geology. He will notice at some length the imperfection of the geological record, especially in the earliest times. He will advocate the continuance of that work in detail which has been the cause of our best discoveries in the past. Doubt will be thrown upon the advantage of too rigid an adherence to uniformitarianism. Lastly, he will discuss the advantage of geology as an instrument of education. In the work of the Section, more prominence than usual will be given to the reports of the research committees, several of which are likely to lead to considerable discussion. The excavations at Hoxne have been successful in proving the relation of Palæolithic man to the glacial epoch, besides yielding new evidence as to alternations

of climate during the Pleistocene period. Sir William Dawson will deal with pre-Cambrian fossils, and a number of papers are promised on local geology.

In Section D (Zoology), the President (Prof. Poulton) will take as his subject a naturalist's contribution to the discussion on the age of the earth. His object is to show that the appearance in time, and succession, of the various groups of animals in every way supports evolution, but an evolution which took its rise in a very much more distant past than the Cambrian or Laurentian. The general result will be to strongly support the geologists against certain of the physicists. The other arrangements in Section D are: On Friday forenoon a debate on Neo-Lamarckian theories, probably introduced by Prof. Lloyd Morgan; and in the afternoon, a report and discussion on the fauna and flora of the Irish Sea; on Saturday, a report on the migration of birds, and then a dredging and trawling expedition in Liverpool Bay; on Monday forenoon, a debate on the ancestry of vertebrates, introduced by Dr. Gaskell; on Tuesday forenoon, a joint meeting with the Botanical Section for a discussion on the cell theory; while Wednesday and the remaining afternoons will be occupied by papers which have been announced by Prof. Minot and Messrs. Macbride, Newstead, Benham, Traquair, Hartog, and others. Sir William Dawson brings some fresh evidence in regard to *Eozoon*, and Dr. Traquair will give the latest information in regard to *Palæospondylus*, illustrated by recently acquired specimens and an enlarged model.

In Section E (Geography), the address by the President (Major L. Darwin) will deal largely with African railways. Papers have been promised by a number of travellers and others, including Mr. Moir (climate of Nyassaland), Mr. Heawood (African geography), Rev. C. H. Robinson (Hausaland), Mr. Fletcher (journey in Tibet, with Mr. Littledale), Mr. J. Coles (photographic surveying), Mr. Vaughan Cornish (sand-dunes), Mr. H. N. Dixon (marine research in North Atlantic), Mr. E. A. Fitzgerald (the New Zealand Alps), Mr. A. W. Andrews (geography and history in schools), Mr. A. J. Herbertson (geographical teaching), Prof. J. Milne (Japan and its earthquakes), Dr. H. R. Mill (local geography of England), Mr. Harry Lake (the Gambia and Senegal). It is hoped that papers will also be offered by Count Pfeil, Mr. Lewin, Mr. Howard, Colonel Woodthorpe, the Archduke Ludwig Salvator, Captain Vandeleur, Colonel Trotter, Mr. Hull, and Mr. Fowler. There will also be reports on African climatology and on geographical education.

In Section G (Mechanical Science), the President's address, on Thursday morning, will be followed by a report of the Committee on Tides, and after that comes a paper by Mr. G. F. Lyster on the Dock development of Liverpool. There will be other papers on local engineering works. the Atlantic steamships, the overhead railway, and the Liverpool waterworks. Papers are also announced by Mr. Wolf Barry on the Tower bridge, by Prof. Mengarini on the electric light and tramway systems of Rome, and by Mr. A. R. Sennett on horseless carriages—a number of which, it is expected, will be shown in operation.

In Section H (Anthropology), following the precedent which proved so successful at Ipswich last year, it is proposed to group the proceedings of the Section round a limited number of large questions which seem more particularly ripe for discussion at this time. The fact that the President, Mr. A. J. Evans, the Keeper of the Ashmolean Museum at Oxford, has taken a leading part in recent exploration and discovery among the remains of early civilisation in the Levant, and that a public lecture by Prof. Flinders Petrie, last year's Sectional President, is announced on a kindred subject, suggested the early history of mankind in the Mediterranean as an appropriate subject for discussion.

The President's address, which will be delivered late in the morning of Thursday, may be expected to deal, in part at least, with this department of anthropology, and will be followed by lantern demonstrations of recent Palæolithic discoveries in North-east Africa and elsewhere. Friday will be devoted to physical anthropology, and the opportunity will be taken of commemorating the centenary of the birth of Dr. Retzius, the celebrated Swedish anthropologist, whose son, himself a distinguished observer, has signified his intention of probably being present. Dr. Dubois will discuss *Pithecanthropus*, and Dr. Brinton and Dr. Sergi the physical aspect of Mediterranean and, especially, of North African races. Dr. Topinard is expected to be present, and a communication is promised on the pygmies of Central Africa. Saturday is assigned to reports and discussions on the collection and registration of ethnographic data, and a resolution in favour of an Imperial Bureau of Ethnology will be brought forward by Mr. C. H. Read, of the British Museum. Folk-lore and descriptive anthropology will also be represented on this day. Monday opens with papers on the early distribution of copper and of iron in Europe and the Mediterranean; followed by a general discussion of the modes of the transference of culture, and illustrated by an exhibition of the early ornament of North-west Europe. On Tuesday, a general discussion of early Mediterranean civilisation has been arranged. Communications are expected from the President, Dr. Montelius, Mr. Salomon Reinach, Dr. Naue, Dr. Stolpe, Prof. Ridgway, and others. On Wednesday, Prof. Flinders Petrie's proposal of a national ethnographic storehouse comes up for discussion, and a number of separate communications will be presented. It is hoped that it may be possible to announce somewhat in detail the probable course of each day's discussion during the meeting.

In Section I, the President (Dr. Gaskell) will give his address and a paper on the origin of Vertebrates on Monday morning, and after that a joint discussion with the Zoological Section will take place. Other discussions have been arranged within the Physiological Section: (1) on the organisation and correlation of bacteriological work, to be opened by Dr. Sims Woodhead; and (2) on the presence, and effect, of bacteria in various food matters, by Dr. Kanthack. Profs. Boyce and Herdman will bring forward a report on oysters and typhoid; and various other papers are announced dealing with excitability in muscle and nerve, metabolism, gas exchange, &c.

In Section K, the President (Dr. D. H. Scott) will deal in his address with the present position of morphological botany, discussing modern work bearing on the origin and affinities of the main groups of plants with reference to fossil as well as to recent forms. The chief features, after the address, will be (1) an afternoon lecture on the geographical distribution of plants, by Mr. W. Thiselton-Dyer, Director of the Royal Gardens, Kew; (2) the joint discussion with Section D on cell and nuclear structures, to be opened by Prof. Farmer; and (3) a discussion on the ascent of sap, to be opened by Mr. Francis Darwin of Cambridge.

We understand that Prof. Flinders Petrie's aim in his evening discourse, entitled "Man before Writing," is to bring forward the character of civilisation in different countries just before the introduction of writing, to show what man is and does before the great change produced by unalterable record and transmissible message: also to point to the methods of research where no written record remains. This period covers what is now the main field of interest in European history, and also the culture of the new race in Egypt. Dr. Francis Elgar's lecture will be on "safety in ships," and Prof. Fleming's lecture to the operatives will be on "the earth a great magnet."

W. A. Herdman.

THE TOTAL ECLIPSE OF THE SUN.[1]

II.

KIÖ ISLAND, *August* 8.

A LOVELY morning. The sun remained unclouded till long after eclipse time, giving thereby an additional proof of the advantage to us of the short nights. There is no time either for any considerable reduction of temperature or for the accumulation of any great amount of moisture in the air; hence unclouded sunrises, and the sun strikes hot soon after rising.

The beautiful harbour in which the *Volage* is lying looks its best in early morning, as the face of the nearly vertical cliff, which swarms with bird life, lies nearly west and south, facing eastwards.

I am glad to say that the last adjustments have been made, the last demonstrations given; numerous rehearsals have landed us in the perfection of drill; the parties all know their stations, and all necessary forms

FIG. 5.—The *Volage* at anchor.

have been written out. We are going then to-day to "stand easy," and take some rest in preparation for the fateful to-morrow.

I take advantage of the pause to continue my notes. I confess I am keenly interested in our now tremendous eclipse party. I will first of all, then, deal with its progress, and especially with the final arrangements made for the larger instruments.

The *personnel* of each fixed instrument is as follows. Mr. Fowler has charge of the 6-inch prismatic camera, and he receives the following assistance.

As timekeeper Sub-Lieut. Beal offered his services, and his duty is to give Mr. Fowler warning some seconds before the commencement of totality, and to record the times of exposure of the fifty plates intended to be used. Roberts, an A.B., acts as exposer, taking off the cap from the prism at given signals. To economise the greatest amount of time, two marines stand to Mr. Fowler's right and left, to hand and receive the slides as they are inserted in and drawn out of the camera. The exposures to be made are generally very short, in fact they are all snap-shots with the exception of only two, one of them extending to half a minute.

The plate-holders are ten in number; each is capable of holding five plates, which are exposed by slipping them in turn into the focal image; this operation is controlled by a catch. The hut in which this instrument is housed is one brought out from home; the framework is covered with waterproof canvas so arranged that the roof can be removed at any time for observation. A dark room for photographic work is also attached.

The instrument under the charge of Dr. W. Lockyer is also a prismatic camera, but of 9 inches aperture, and rather differently mounted. The tube carrying the camera, prism and lens is fixed horizontally, and the light is thrown on to the prism by means of a siderostat. The work intended to be done is to obtain ten photographs in all; two snap-shots, seven with different times of exposure, the greatest amounting to thirty seconds, and lastly, a "dropping" plate. This last-named is intended to be exposed as near as possible ten seconds before the end of totality, and carried through until fifteen seconds after, the plate being moved slowly in the direction at right angles to the length of the spectrum. The object of this motion is to obtain an unbroken record of the changes in the spectrum during this interval of time.

As timekeeper for this instrument Midshipman Bruce has been selected, his duty being to keep Dr. W. Lockyer informed of the time a few seconds previous to totality, and also to note the times and lengths of the exposures made during totality. One of the ship's carpenters, Sullivan, operates with the cap in front of the prism, acting on instructions given to him by the observer. Two bluejackets are also employed in handing and replacing the dark slides as they are required.

The whole work of using the integrating spectroscope is left to members of the ship's company. Lieut. Martin has been selected as director, and he has as his assistants Midshipman Woodbridge as "exposer," Midshipman Brendon as timekeeper, and Midshipman Silvertop to keep the sun's image on a small screen for the purpose of correct orientation.

The instrument is set up on a board inclined at the angle representing the altitude of the sun at the time of eclipse, and movable in azimuth by means of a milled-head-driving screw turned by hand. By this means the collimator can be directly pointed towards the sun, which does away with the necessity of using a second siderostat, and this is all the more important because we have not a

[1] Continued from page 400.

second siderostat. The intention is to make three exposures with this instrument.

The whole apparatus is housed in a tent made by the carpenter out of ship's material, spare spars and a sail. The peculiar appearance of the hut has resulted in its being named by the sailors Porcupine Cottage. The hut for the 6-inch, which adjoins it, is called the Town Hall.

With regard to the other branches of work, in some of which the numbers assisting are large, the senior volunteer in each has been made responsible for the preparation and subsequent signing of forms, and representative in general of the party. The Chaplain, the Rev. E. J. Vaughan, whose interest has been unflagging throughout, has been good enough to act as intermediary between these representatives and myself, so that the closest touch has been kept. It was thought desirable that in addition to acting on the general instructions, each party should know the special points on which information is desired. A request for detailed answers to certain questions has been therefore placed in the hands of the head of each section.

I have said that this morning was lovely; yesterday — the 7th — was not by any means a pleasant and bright day, but the rain managed to keep away and allow work to be carried on in the camp, in which the preparation and the rehearsals have been vigorously continued. The first boat leaves the ship at about five each morning, so as to secure drill at eclipse time, and from this time onwards there is a continual passage of boats from ship to camp and back again, as the various observers are released from their work, which goes on incessantly, not only on board among the guns and masts, but in the fjord, in the shape of firing and boat parties, the firing being strongly objected to by the inhabitants of the "loomery," which is hard by.

The birds, which in our stay we have become acquainted with, are of several kinds. Foremost among these is the white seagull, which has its home on the crags and ledges of the cliff to the west of the *Volage*. These birds literally swarm here, but apparently seem to be divided into distinct societies; indeed, on the cliff there are three or four separate "loomeries," and the birds in each of them always keep together and seldom, if ever, intermix with those in others. At apparently fixed times they fly down from their ledges and form a teeming, hurrying, clamorous throng, eddying in front of the face of the cliff. The young birds at the time are just beginning to fly, so the noise is perhaps greater than usual. After we had been here a few days they all became very tame, and swam around the ship. On Starvation Island several young ones were found; these could be easily located by paying attention to the utterances of the parent birds flying overhead, which became louder and louder the nearer the right spot was approached.

The young birds were found always in small pools between the rocks, generally lying under small bushes of grass overhanging them. The bluejackets, when ashore, caught many in this way, and it was amusing to see these birds walking about the forecastle as if owners of all they surveyed. An amusing incident occured on the evening the *Volage* arrived from Vadsö. Lieut. Martin and Sub-Lieut. Beal, on going on board the sailing cutter, found a dead gull in the bottom of the boat; on further examination, no less than 20 to 25 more were found stowed away in the stern. On making inquiries of the bluejackets as to their presence, they replied that they had collected them for supper in case the ship did not arrive that night, as provisions were rather short. The ship, however, did arrive, so that fried gull was not indulged in.

The shag, or green cormorant, abounds also in great numbers. These birds are far from beautiful, and were disliked by everybody. Many of them were too fat to fly properly, and when disturbed they managed to make themselves scarce by flopping over the surface of the water. The reverse was the case with the prettily marked oyster-catchers; these were always watched with interest, and there were five which greeted the party daily as it landed on Kiö Island. These birds are noted for being very self-possessed, cautious, and deliberate; and any event out of the ordinary arouses their curiosity, and incites them to make closer examination. Of the other birds seen, some were quick-moving sea-swallows, and a few ducks skimming occasionally along the fjord.

Fig. 6.—The Siderostat and the 9-inch Hut.

On our island, Kiö, there are several Lapps who continually watch our movements. In the small bay on the western shore there is one small hut in which about five, including one woman, live; while generally some of the others encamp in small curiously-looking huts near by; or either sleep in their boats or on skins ashore. In the bay to our south-east, on the other side of the fjord, there is quite a large Lapp encampment, and it is from this that most of our visitors come. The accompanying group shows many of these. This photograph was taken instantaneously, and without any preparation as regards grouping, and shows them as they sat watching us erecting the huts and instruments. At this time

of the year they are generally occupied in fishing, and they sometimes bring up very fine selections of fish to our camp, which are generally bought by the steward for the ship's mess. The peat also on the island had been cut and stacked, so that this also formed at an earlier period of the year part of their daily work.

We are quite out of the world here, and till yesterday had no information as to what the other parties were doing at Vadsö. We knew that the remaining ships of the Training Squadron had arrived on Wednesday, and the booming of salutes from time to time informed us that other men-of-war had arrived. We could get no information concerning the astronomical parties, and no observer could be spared to make inquiries.

But late on Tuesday, when we had finished sketching drill, and were experiencing our only fog, a syren and the quick reply of the ship's bell told us that some vessel was approaching. Shortly afterwards we made out one of the small steamboats which ply from Vadsö to the fjords on the south side; she subsequently came alongside. We saw that Dr. Common and Sir R. Ball were on board, and I hailed them from the poop. Captain King Hall hospitably invited them on board, but the invitation was declined owing to the weather conditions, which were not improving, and the lateness of the hour. They had still to run twelve miles to reach Vadsö.

Captain King Hall invited Dr. Common, Sir R. Ball, and Mr. Downing to come over from Vadsö yesterday to lunch and see our camp. Dr. Common was too busy in setting up and adjusting his instruments, but Sir Robert Ball and a small party paid the ship a visit. We had previously arranged that the final dress rehearsals should take place in the afternoon, so our visitors were just in time to see the drill gone through. All timekeepers, chronometer, stop-watches, and deck-watches were ready. Each man was at his appointed post; the sketchers stood to the west of the camp on the higher ground; the disc observers were blindfolded and in their places, while each of the other instruments was attended by its full staff. These rehearsals must appear very curious to those unacquainted with eclipse work, and certainly our visitors saw the very perfection of drill. The routine gone through was exactly the same as if the eclipse was taking place, with the exception that no plates were actually exposed. After these general rehearsals the observers at each special instrument were put through their facings. Our visitors seemed to be rather astonished at the great amount of work that will be done if the weather only proves favourable to-morrow.

We gathered from Sir R. Ball that all the arrangements at Vadsö were nearly complete, and that Dr. Copeland's 40-foot tube was already in position.

The time arrangements have to be somewhat complicated, for the reason that it is desirable to begin the exposures with the prismatic cameras ten seconds before totality. We have then, if possible, to make a correction should the *Nautical Almanac* times be slightly out. The Admiralty authorities were good enough to put on board at Portsmouth a first-rate chronometer for our special use, and Lieut. Martin and Sub-Lieut. Beal have been unremitting in their endeavours, by taking sights and noting rates, to give us G.M.T. within a small fraction of a second.

FIG. 7.—The Integrating Spectroscopic Camera.

Before totality we have two chances of checking the *Nautical Almanac* times; by observing the first contact spectroscopically, and, failing this and more doubtfully, by observing the crescent when it covers an arc of 180°; this, it has been calculated, should occur 7m. 10s. before totality. It has been arranged that after the first contact the true G.M.T. will be called out from time to time as required, and also each minute before totality, corrected, if necessary, in the way I have already stated. In this way the special timekeepers of the prismatic cameras will be able to begin their work at the right moment before the general signal for totality, "Go," is given.

I am sorry to say that the eclipse-clock has broken down; the ship's armourer has vastly improved its going, but it has received some damage, so that I cannot rely on it. It is not good for a clock to be used only once in five years or so! So we fall back on stop-watches; and here I must state my obligations to Mr. Tripplin for the loan of a fine chronograph, which makes our stock complete, and enables us to feel certain that at one station or another the exact duration of totality will be caught.

My intention is before totality, in case we miss the first contact, to set one of the stop-watches going when the crescent covers as near as may be 180° of arc; this will give us time to correct the *Nautical Almanac* if necessary. Another will be handed to our two excellent timekeepers to replace the eclipse clock.

Two things have been strongly impressed upon me in my eclipse experience. The first is always to arrange the work so that everybody can have 30 seconds in which to observe the phenomena of the eclipse with the naked eye; the second, to take out no case which weighs more than 50 or 60 lb.

The importance of the first was forced upon me in 1871, when Captain Bailey, who travelled 400 miles to our camp to help us, and volunteered to act as timekeeper, turned his back resolutely on the eclipse and saw absolutely nothing of it, because in the preliminary drills he found he had a difficulty in picking up the time again when once he looked away from the face of his chronometer.

This time then we have a relay of timekeepers, one replacing the other at "60 seconds more"; this signal is given by both. The one who gives the time has his back to the sun, the other will see what he can. At my signal, "Go," depending upon the final disappearance of the photosphere as seen in a $3\frac{3}{4}$ with neutral tinted glass, the timekeeper first on duty is to sing out "105 seconds" and give the time every 5 seconds, "100 seconds," "95 seconds more," and so on.

The question of lamps during the eclipse is settled in the following way. If the sky be quite clear, some will certainly be wanted for the timekeepers in the huts, and for reading the fine graduations of the delicate chemical thermometers which I have brought with me. But if the sky be not clear, then others may be wanted too. So Captain King Hall has arranged to have ten lamps, each in charge of a bluejacket, in reserve, in the middle of the camp, so that anybody who wants one has only to say so to be immediately supplied.

A guard of five marines has remained permanently at the camp during our stay. They are generally dressed in most arctic-looking costumes known as "lammy suits." These are nothing more than a pair of trousers and jacket (with a hood), made out of ship's blankets, worn over the ordinary dress; they were invented, I believe, by the sailors when they made a long stay at Spitzbergen. They seem to be grand clothes for a camp, and in fact one of the marines seems to be seldom out of his—he appears to revel in the warmth it gives. Besides acting as guard to the camp, the marines are useful in many other respects; for instance, in addition to signalling for us, they are very good cooks, and all our cocoa, soups, meat, &c., brought from the ship, only needs to be handed over to them to be served up in our tent in a very appetising condition.

Fig. 8.—Our Lapp Visitors.

Since the eclipse begins so early on the morrow, arrangements have been made that a few of us should sleep in the camp to-night, and thus come under their special care; the ship's company will come over in the morning.

J. Norman Lockyer.

(*To be continued.*)

PROFESSOR A. H. GREEN, F.R.S.

Geological science has sustained a very serious loss in the death of Alexander Henry Green, Professor of Geology in the University of Oxford. He was born at Maidstone on October 10, 1832, and after receiving his early education at the grammar school at Ashby-de-la-Zouch, he entered Gonville and Caius College, Cambridge. There he gained the place of sixth wrangler in 1855, and was elected a fellow of his college. Although mathematics had gained for him his high position in the University examination, yet geology had taken some hold of him. His interest in the subject had been awakened in Leicestershire, and the eloquent teachings of Sedgwick had further attracted him to the science.

In 1861 he obtained the appointment of Assistant Geologist on the Geological Survey of Great Britain, and was engaged for some years in mapping portions of the midland counties, near Aylesbury, Buckingham, and to the east of Banbury. Three years later his memoir on the geology of the country around Banbury was published; and although since then some modifications have been made in the grouping of the oolites, his careful statement of facts rendered the work of permanent value. Leaving these regions of lias and oolites and glacial drifts, he was transferred to the carboniferous districts of Derbyshire and South Yorkshire. Here he laboured for a number of years, practically superintending the survey of the great coal-field, and training several junior geologists to assist in the work. In the end he produced, with the aid of his colleagues, the large and exhaustive memoir on the Yorkshire coal-field, published by the Geological Survey. In 1875 he resigned his post on this survey on being appointed Professor of Geology in the Yorkshire College at Leeds. Ultimately he became

also Professor of Mathematics at the same college. Although by no means a voluminous writer, he contributed occasional papers to the Geological Society and to the *Geological Magazine* on the carboniferous rocks of the north of England, on sub-aërial denudation, on the geology of Donegal, the Malvern Hills, &c. His practical knowledge of geology, his clear head, and sound judgment rendered his advice on matters of engineering geology of great service. Consequently he was engaged here and there in many important undertakings, more especially in reference to coal-mining, water-supply, &c. This work, perhaps unfortunately, was needful, for it exhausted those energies that might have been more advantageously directed to the advancement of knowledge. Professorships of geology are not, however, lavishly endowed. Visiting portions of South Africa in the course of practical work, he was able to obtain a considerable insight into the geology, and brought his results before the Geological Society. Not the least important of his labours was his manual of Physical Geology, admittedly the best English work on this branch of the science, and one which reached a third edition in 1882. The companion volume on Stratigraphical Geology was never completed, and indeed other publications perhaps rendered it unnecessary.

After the resignation of Prof. Prestwich in 1888, he was chosen to succeed him in the chair of Geology in the University of Oxford. Here he found abundance of work to do in the arrangement of the geological museum, in his lectures and class excursions. A large task, indeed, still remains to be done in the examination of many treasured specimens that have never yet been exhibited. Prof. Green took great interest in this work, and in the acquisition of new specimens. Only recently he spent some time in selecting a series of fossils from the valuable collection of the late Thomas Beesley, of Banbury, which had been presented to the Oxford Museum by Mrs. Beesley.

Prof. Green was elected a Fellow of the Royal Society in 1886, and he served on the Council during the years 1894–95. For many years he gave lectures on geology at the Military School at Chatham; he was an examiner in geology for the University of London; and had been President of the Geological Section of the British Association at Leeds in 1890.

Early in August he was afflicted with a stroke of paralysis, and a second attack terminated his busy and useful life on the 19th of the month. Eminently genial and kind-hearted, he will long be missed by his many friends. H. B. W.

NOTES.

AT the Leyden International Zoological Congress, held last year, it was decided that the next meeting of the kind should take place in England, in September 1898, and that Sir William Flower, Director of the British Museum (Natural History), should be its President. We now learn, through the *Times*, that it has been determined that the 1898 Congress, the fourth of the series, shall meet at Cambridge, under the auspices of the University, simultaneously with the International Physiological Congress, which has arranged to go there in that year. London and Edinburgh were named as places of meeting in connection with the Zoological Congress, but it was felt that there were certain advantages in holding an international meeting of this character in a University town within easy distance of London, rather than in London itself. The organising and reception Committee consists of Prof. Alfred Newton, President; Mr. Adam Sedgwick, Vice-President; Messrs. J. W. Clarke and Sydney J. Hickson, Treasurers; and Messrs. S. F. Harmer and Arthur E. Shipley, Secretaries. With reference to the two prizes which will be awarded at the Congress for the best zoological papers, the Paris members of the permanent Committee suggest that the subject for the Tsar Alexander III. prize, which will be given for the first time, shall be "The Study of the Ruminant Mammalia of Central Asia, from a Zoological and Geographical Standpoint"; and that for the Tsar Nicholas II. prize, which was awarded last year at Leyden for the first time, the paper shall be "An Anatomical and Zoological Monograph of a Group of Marine Invertebrates." These subjects are, however, in the nature of proposals which may be modified, since the Paris Committee will be glad to receive counter-suggestions and to learn the views of zoologists before making public the detailed programme of the prizes.

THE annual conference of the Iron and Steel Institute opened at Bilbao on Tuesday, under the presidency of Sir David Dale. Various papers were read, and in the evening a grand reception was given by the municipal authorities in honour of the Institute.

INFORMATION has been received through Reuter's agency of the finding of an extensive gold-bearing quartz reef at Cape Broyle, Newfoundland. The analysis shows nearly three ounces of gold to the ton of quartz, and over one ounce of silver. The barrels of quartz sent for analysis were taken at random.

DR. E. S. HOLDEN announces in *Science* the following gifts to the Lick Observatory:—By Miss Caroline W. Bruce, of New York City, a sum of money to procure a large comet-seeker, and to provide photometers for visual use with the thirty-six-inch equatorial; by Mr. Walter W. Law, of Scarboro'-on-Hudson, a liberal gift towards providing for the publication of the Observatory Atlas of the Moon, mentioned in the *Publications*, vol. viii. p. 187.

THE forty-first annual exhibition of the Royal Photographic Society is in course of preparation, and will be opened to the public on Monday, September 28. On Saturday, September 26, there will be a private view, followed in the evening by a conversazione, at which the President and Council will receive the fellows, members, and their friends. The judges this year in the technical section are Captain Abney and Messrs. Chapman Jones and Andrew Pringle. Exhibits must be delivered at the Society's rooms, at 12 Hanover Square, not later than the morning of September 10.

PARTICULARS of the International Horticultural Exhibition to be held in Hamburg, from May to September next, have now come to hand. The Committee proposes: (1) a Permanent Exhibition, out-of-doors and under cover, from the beginning of May 1897, to the end of September, 1897; (2) a Spring Exhibition, from May 1 until May 7, 1897; (3) a Special Exhibition of plants, flowers, and vegetables, from May 30 until June 3, 1897; (4) a Special Exhibition of plants, flowers, and shrubs, from July 2 until July 6, 1897; (5) a Special Exhibition of plants, flowers, and fruits of the season, from July 30 until August 3, 1897; (6) a general Autumn Exhibition from August 27 until September 5, 1897; (7) a general Fruit Exhibition, from September 17 until September 30, 1897.

THE seventh annual general meeting of the Federated Institution of Mining Engineers is announced to take place at Cardiff on September 15, 16, and 17. Some thirteen papers are on the agenda, and many excursions have been arranged. An invitation has been given to the Federated Institution, among others, by the Canadian Mining Institute, to hold a meeting in Montreal at about the date of the meeting of the British Association in Toronto next year; but before replying, the Secretary of the Institution is anxious to learn the names of those who may be expected to be present on the occasion.

Kief has been selected as the place of meeting of the tenth conference of Russian Naturalists and Physicians. The conference will last from August 21 to August 30, 1897. A grant of over £400 has been contributed by the University of St. Vladimar in Kief towards the expenses.

Good progress is being made by the Russian National Health Society in the matter of the Jenner Commemoration of October next. The centenary work, containing a life of Jenner and translations of all his works, as well as an historical notice of the development of vaccination in Russia and other European countries, is likely to be a volume of much interest and value. It will be illustrated by over a hundred figures, including many reproductions of Jenner's original drawings, portraits of Jenner, and views of the Berkeley neighbourhood. The Society, under whose auspices the commemoration is to take place, is already in receipt of a large number of loans and gifts for the exhibition which it is proposed to hold in connection with the celebration, and these have come from well-nigh every part of the world. England, it is said, is not too well represented by exhibits.

News comes from Russia of another medical society having received the, in that country, necessary Imperial approval of foundation. It is to be known as "The Society for Combating Infectious Diseases," and will be under the patronage of the Princess of Oldenburg. The society will resemble the Russian National Health Society, in that it will admit both lay and medical members.

According to *Science*, an observatory for terrestrial magnetism has been established in connection with the astronomical observatory at Munich, and Dr. Franz von Schwarz has been appointed director. *Science* also states that the Observatory of the School of Technology at Karlsruhe is to be removed to Heidelberg. The Director of the Observatory, Dr. Valentiner, has been made a Professor in the University of Heidelberg.

A magnetic survey of Maryland is being made by Dr. Bauer, the editor of *Terrestrial Magnetism*, under the auspices of the State Geological Survey.

The *Engineer* states that Colonel Home, C.S.I., Royal Engineers, has been engaged by the New South Wales Government as an expert to advise on the subject of water conservation.

The *British Medical Journal* learns from Amoy, China, that Dr. Yersin has been experimenting with his plague serum. Up to date he is reported to have cured more than twenty plague patients. The cures are reported to be marvellous, as many of the patients were in high fever, the buboes fully developed, and the sufferers in a comatose state. In Canton Dr. Yersin, on July 1, 1896, according to Bishop Chausse, effected a remarkable cure on a very unmistakable and severe case of plague. After showing the Amoy doctor his methods of injection, he returned to Saigon. It is stated in the newspapers in China that it takes six months to prepare the serum; that Dr. Yersin first inoculates rats and then horses, from which sources he obtains his fluid.

The subject of the Baumgartner Prize for 1899, awarded by the Vienna Academy of Science, is "the extension of our knowledge of ultra-violet rays."

The Leopolinisch-Carolinische Academie of Halle is, it is stated, about to publish Cuvier's first work, which is on the edible crabs of the French coast. It dates from the year 1788. A number of letters of Cuvier are in the possession of the Academy, and these also it is intended to publish.

The University of Moscow has been presented with a portion of the collection of butterflies of the late Prof. A. M. Butljero, and the Museum of Natural History, Berlin, has had bequeathed to it, by the late Julius Flohr, that gentleman's collection of Mexican insects.

Some one once rather unkindly said that one half of the British population was always endeavouring to shut up the other half in asylums of one kind or another. Though this remark may be a trifle exaggerated, it may be applied with some truth if societies or associations be read for asylums. The latest association which has appealed for our support is for the Harmonious Development of Faculties. The Association aims at bringing about a clearer apprehension of the co-relationships of physical, moral and intellectual faculties. Anything that contributes to the harmonious development of these is good; anything that hinders this development is evil; these are briefly the ethical rules of the Association. The Committee believe that they are spreading a philosophical truth which will have an elevating influence over men's minds. They therefore wish us to draw attention to the existence of the Association, and this we have now done, leaving to our readers the contemplation of the doctrine to which we have referred. The Hon. Secretary of the Association is Prof. M. Deshumbert, Camberley, Surrey.

Dr. W. L. Abbott, of Philadelphia, has been well employed during the past eight years in exploring various parts of the Old World, and sending his collections to the National Museum at Washington. Mount Kilima-njaro and the adjoining districts of East Africa were the scenes of his first investigations, after which he visited the Seychelles, and the neighbouring islands of the Indian Ocean. He then proceeded to Northern India, and passed two years in Cashmere, Ladak, and Turkestan. From all these localities numerous collections of natural history and ethnology have been transmitted to Washington, where the members of the staff of the National Museum are busy in working out the results. Two of their reports on the birds collected by Dr. Abbott have just reached us. One of them, by Mr. Ridgway, describes the specimens obtained in the Seychelles, Amirantes, Gloriosa, Aldabra, and other adjacent islands, many of which had not been previously visited by a naturalist. In Aldabra, generally known as the home of gigantic tortoises, Dr. Abbott met with forty-five species of birds, several of which are representative forms peculiar to that island. In a second memoir Mr. Richmond gives us an account of 746 "well-prepared specimens" which Dr. Abbott has accumulated in Kashmir, Ladak, and Baltistan, and refers them to 188 species. Most of these are, of course, well known to Indian ornithologists, but Mr. Richmond ventures to describe as new a Blue-throat from Ladak, under the name *Cyanecula abbotti*.

Dr. Nicola Terracciano has contributed to the Transactions of the R. Accademia delle Scienze fisiche e matematiche, of Naples, an important memoir on the flora of Monte Pollino and the surrounding district. This group of mountains, situated between Calabria and the Basilicate, has for some time attracted the attention of Neapolitan botanists, and the number of species in its flora now amounts to 1468, exclusive of varieties. Dr. Terracciano notes as new to the Italian flora, *Gagea minima* and *G. amplyopetala*, and he describes four altogether new species, namely *Fritillaria pollinensis*, *F. intermedia*, *Ornithogalum ambiguum* and *Narcissus pollinensis*, together with many other forms which he considers varietal.

The estimation in which certain gramineous species are held varies much in different countries. For instance, *Holcus lanatus*, which in Britain is universally regarded as a weed, though it intrudes abundantly upon many of our pastures, is deliberately sown in mixtures of meadow-grass seeds in France. The *Agricultural Gazette of New South Wales* (vii. 5) cites another example in the tufted hair grass (*Deschampsia cæspitosa*, Beauv.,

or *Aira cæspitosa*, Linn.). This species is locally known in England as tussock grass, and as "bull faces" or "bull pates," and efforts are constantly made to extirpate it from our permanent pastures. In Australia, however, "it affords a fair pasturage if periodically burnt down." Graziers on and near the Australian Alps have been asked to send notes of their observations of this species, as it is regarded as quite possible that the Australian plants differ in forage value from those of the northern hemisphere. The culms are sufficiently tough to permit of door-mats being made from the hay.

WHAT is known as the "shade-tree insect problem," in the Eastern United States, forms the subject of an illustrated bulletin of the Department of Agriculture at Washington. The great abundance of insects which attack shade-trees was a noteworthy feature in many of the cities in the summer of 1895. In almost every low-lying town from Charlotte, N.C., north to Albany, N.Y., the elm-leaf beetle *Galerucella luteola* defoliated the English elms, and often the American elms. The bagworm (*Thyridopteryx ephemeræformis*), the white-marked tussock moth (*Orgyia leucostigma*)), and the fall webworm (*Hyphantria cunea*) are conspicuous amongst the depredators. Some species of trees suffer much more than others, the beeches, hornbeams, and alders appearing to have few insect enemies. Spraying and banding of trees and other checks are being employed, and one of the Washington newspapers has advocated the formation of a tree protection league amongst the citizens.

A CORRESPONDENT in the *Grahamstown Journal* tells how he cleared his garden of a pest of locusts. A number of diseased insects were obtained and ground into a fine powder, which was then placed in a bucket of water. Some of the mixture was poured on a few locusts of a fairly good-sized swarm, and before many days had elapsed numbers of the locusts were found dead, and eventually the garden was quite clear of the pest.

ON account of the great success of the botanical models made by the firm, Herrn. R. Brendel, in Berlin, the same firm is now constructing zoological models out of papier-mâché, some of which are exhibited in the Berlin Exhibition this summer. For instance, there is a model of the ordinary house-fly (*Musca domestica*) thirty times life-size; it is very accurately made, and all its parts are beautifully worked and distinct, making it unnecessary to take it to pieces. By means of a small piece of mechanism the spreading of the wings can be demonstrated. There is also exhibited, in a series of eight models, a plaster representation of the development of the frog, each being ten times life-size; they are all so arranged that they can be lifted off their supports and examined more minutely. With the help of such useful models as these, students of zoology will be more easily able to grasp some points which cannot always be obtained from pictures or diagrams. These models should also be found most useful in schools where the pupils do not often come in contact with museums.

IN Italy, almost the only instruments used for the study of earthquake-pulsations are long and heavy pendulums. The greater the length the more steady is the bob during movements of the ground, and the heavier the bob the more readily is the friction of the recording pens overcome. In the last number of the *Bollettino* of the Italian Seismological Society (vol. ii., 1896, pp. 62–65), Dr. A. Cancani describes the latest form of seismometrograph constructed under his superintendence. Two instruments have been made, one for the geodynamic observatory at Rocca di Papa, and the other for that at Catania. The former is 15 metres long and 200 kg. in mass, the latter is 26 metres in length and has a mass of 300 kg.; in other respects they are almost identical. The suspending wire of the pendulum passes at its lower end through slits in the short arms of two horizontal levers. The slits are at right angles to one another, but the levers are bent at an angle of 45° in opposite directions, so that the pens at the free ends of the long arms write their component records side by side on the same moving band of paper. The paper is driven at the rate of 60 cm. an hour, a velocity great enough to allow the individual undulations to be examined, and the times of the different phases to be determined with considerable accuracy.

THE restlessness or alarm shown by birds and animals before the occurrence of an earthquake sensible to man is now well known, and is probably due to the very small tremors which precede the larger vibrations. In an interesting paper (*Boll. Soc. Sismol. Ital.*, ii., 1896, pp. 66-74), Dr. A. Cancani has collected a large number of examples observed in Italy. He points out besides the important fact that, while most animals are disturbed during and after an earthquake, it is only at some distance from the epicentre that they exhibit any signs before the shock is perceptible to man. The explanation Dr. Cancani gives is that the tremors move with a greater velocity than the large vibrations, but that a considerable space must be traversed before they have outraced the latter by several seconds.

IN the *Bulletin* of the Constantinople Observatory for January 1896, Dr. Agamennone concludes his summary of the earthquakes felt in Turkey during the year 1895 (see NATURE, vol. liv. p. 373). The number of recorded shocks amounts to 400, and these are found to belong to thirty-one seismic centres, the principal of which are near Paramythia, Imam Keuy (Aïdin), and Pergama. In the neighbourhood of Constantinople at least ten earthquakes had their origin, showing that the seismic activity provoked by the great shock of July 1894 has not yet ceased.

WE have received from Prof. G. Vicentini a new and valuable contribution to our knowledge of earthquake-pulsations, consisting of a list of the disturbances registered by his two-component microseismograph at Padua from February to September 1895. Many of these can be referred to known shocks, occurring either in Italy or in neighbouring countries. On three occasions (March 6, June 15, and July 5) the origin of the pulsations is unknown, but the diagrams are similar to those that are produced by earthquakes taking place at a very great distance. Copies of the diagrams corresponding to twenty-two earthquakes are reproduced on a scale two-thirds of the original.

IN the current number of the *Journal* of the Anthropological Institute of Great Britain and Ireland (vol. xxvi. No. 1) Mr. Robert M. W. Swan gives some very interesting notes on ruined temples in Mashonaland. These temples are of the Zimbabwe style; *i.e.* they seem to take the form of circular arcs, if not complete circles. Practically only one he describes—that of the temple at Lundi River—attains to anything like a circular shape, and this is very complete, being only pierced by two openings. The others scarcely reach 180°, and these seem always to be pierced by a doorway. The temple at Lundi River stands on a little knoll about half a mile south of the waggon road, and 300 yards towards the east of the river. It is built of small rectangular, naturally-shaped blocks of granite, laid in very regular level courses. From the fact that the inside finely-built wall supports, to some extent, many of the stones of the outside wall, it is suggested that it is probable both were built at the same time. Mr. Swan took measurements of the different parts of the building. The circumference of the temple was 169 feet $6\frac{1}{2}$ inches, or 17·17 feet $\times \pi^2$ (10 cubits $\times \pi^2$). At no point did the foundations of the temple diverge more than a few inches from a true circle. The two doorways into the building were 60 feet $8\frac{1}{2}$

inches distant from one another, the angles between the doors subtending an angle of 128° 51′ at the centre. One of the doors formed with the centre of the temple a north and south line, so that it is supposed that the wall between these two doors was intended to face the sun when rising at the summer solstice. Many other interesting points of this temple are referred to by Mr. Swan. To give some idea of the great number, he says: "From what I have said it will be seen that, along the 250 miles or so of road between the Lobsani and Lundi rivers, I have visited about twenty temples, or other remains of the people who built Zimbabwe . . . but admitting that I have seen all within a mile on both sides of the road, and that the strip of country traversed is a fair sample, as regards ruins, of this part of Africa, it is evident that the number of ruins of this class in the whole country between the Zambesi and Limpopo rivers must be enormous." Further on he says: "On a hill further on, I found four temples of the same sort, and one little crescent of rough stones carefully oriented to the sun rising at the northern solstice. In fact these temples are so numerous in this part of the country, that one might safely undertake to find a hundred of them within ten miles of Salisbury." Mr. Swan, in a postscript to his paper, suggests that these temples are not temples in the ordinary meaning of the word, but simply religious symbols, analogous, as he says, to our crosses and wayside shrines. The article contains several other points of interest, too long, however, to be dealt with here.

An extraordinary incident is reported in *Engineering*, from Terre Haute, Indiana, by the city engineer, Mr. G. H. Simpson. A street of this town was paved with brick five years ago, the joints being grouted up. The work was done partly during the winter, being finished in early spring. The foundation consisted of broken stone 8 in. thick, above which was a layer of sand 2 in. thick. At the end of last July, with the thermometer standing at about 100° F., a section of the pavement rose like an arch from its foundation, and though water was turned on to it, and openings made to let out any possible accumulation of gas beneath, it maintained its position unaffected. Men were then put to work to repair the pavement, but hardly had they removed the swollen section when, with a loud report, another section of the pavement rose in a similar manner to a height of 7 in. to 9 in.

We have received the fourth yearly report of the Sonnblick Society, containing the results of the meteorological observations made at the summit of that mountain for the year 1895. In addition to the usual obligatory observations, the observer, at the instigation of Dr. Pernter, made a special study of the crackling or humming of the telephone, and by this means, the occurrence of thunderstorms was frequently predicted. The records of this phenomenon have been discussed by Dr. W. Trabert, who finds that in all years, during the winter season, the noise gradually decreases from 7h. a.m. until noon, and then increases until about 9h. p.m.; while in the summer season the minimum occurs about 7h. a.m., from which time the humming steadily increases until 9h. p.m. The only meteorological phenomenon with which the noise can be connected appears to be the diurnal and annual range of the amount of cloud, which it closely follows; whence Dr. Trabert concludes that although it may have some connection with earth currents, it is probably primarily due to the electricity of the clouds. The report also contains good photogravures of a cumulus cloud driven by a strong wind over the Tauris mountains, at an elevation of about 10,000 feet.

A discussion took place some time ago in our columns on "The Alleged Absoluteness of Rotation." In connection with this subject we have pleasure in calling attention to a recent paper by Dr. Benedict Friedlaender and Herr Immanuel Friedlaender, bearing the title "Absolute oder relative Bewegung?" (Berlin: Leonhard Simion), in which the *pros* and *cons* of the three different hypotheses are discussed, as well as the possibility of an experimental solution of the question.

We have received from Prof. Ángel Gallardo, of Buenos Ayres, an interesting pamphlet on Karyokinesis. In it the author presents the physico-mechanical hypothesis of figures of cell-division and some of its consequences, founded on the views of recent writers, without, however, attempting to investigate the influence of this hypothesis on the more important questions of biology.

Four new volumes have been published in M. Léaute's Encyclopédie scientifique des Aide-Mémoire. In "La Distillation des Bois," M. Ernest Barillot describes the plant and processes utilised in the distillation of wood for the production of methyl alcohol, acetic acid, charcoal, tar, &c. A volume entitled "Chaleur et Energie," by M. E. Ariès, is an exposition of the principles of thermodynamics according to a method based upon the postulate that "Un système ne peut décrire un cycle fermé irréversible, à l'aide d'une seule source de chaleur, sans lui *céder de la chaleur* et sans *consommer du travail.*" The work is divided into two parts, the first dealing with the general principles of the science of heat, and the second with thermodynamics. The last chapter is devoted to the description of a general method for the application of thermodynamical principles. Lieut.-Colonel Hennebert contributes to the Series a volume on "Travaux de campagne." In this book, the author reviews the means of organisation of attack and defence of an army in the field, victualling, encampments, and the construction and use of various military works. The same author is responsible for a volume on "Communications militaires." In this, roads, navigable waters, railways, and bridges are examined successively from a military point of view, means of destruction as well as construction being described.

A prospectus has reached us giving particulars of a work on "Submarine Telegraphy," by Mr. Charles Bright, which will, provided a sufficient measure of support is obtained in advance, be published by Messrs. Crosby Lockwood and Son. The book, though based upon Wünschendorff's "Traité de Télégraphie sous Marine," has been thoroughly revised and brought up-to-date, and is practically a new work. Besides being a *résumé* of the science and practice of submarine telegraphy, both from an electrical and engineering aspect, the book contains a complete history of this particular application of science from its birth, practically speaking, in 1850 up to 1895, with a short sketch of that which preceded in land telegraphy, and a prelude concerning all early efforts connected with signalling of any description.

Messrs. Whittaker and Co. are about to publish an authorised translation, by Mr. Lucien Serraillier, of Mr. D. Farman's work on "Automobiles." The work will be fully illustrated, and contain constructional details of the latest developments in this branch of work.

Mr. Quaritch has sent to us his catalogue, dated August, of choice and valuable books offered for sale by him. The list contains particulars of very many rare and choice works relating to most branches of science.

Messrs. Simpkin, Marshall, and Co., Ltd., will, on October 3, issue the first number of *The Avenue*, a monthly illustrated magazine devoted to education, association, and social progress.

The additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mr. A. C. Goude; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. W. Stevens; three Ivory Gulls (*Pagophila eburnea*), a Richardson's Skua

(*Stercorarius crepidatus*) from Spitzbergen, presented by Mr. J. F. Studley; two Variegated Sheldrakes (*Tadorna variegata*) from New Zealand, presented by Sir Walter L. Buller, K.C.M.G.; two Streaky-headed Grosbeaks (*Poliospiza gularis*) from South Africa, presented by Miss Jessie Porter; an Oyster-catcher (*Himantopus ostralegus*), British, presented by Mr. R. Gurney; a Bordeaux Snake (*Coronella girondica*), a Common Snake (*Tropidonotus natrix*, var.) from France, presented by Mr. E. A. Minchin; a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, a Beccari's Cassowary (*Casuarius beccari*) from New Guinea, a Red Kangaroo (*Macropus rufus*, ♀) from Australia, deposited; two Otters (*Lutra vulgaris*) from Ireland, four Cayenne Lapwings (*Vanellus cayennensis*) from South America, purchased; a Chinese Mynah (*Acridotheres cristatellus*) from China, received in exchange; an African Wild Ass (*Equus tæniopus* ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

DOUBLE STAR OBSERVATIONS.—In *Ast. Nach.*, No. 3370, Dr. Doberck, while discussing the elements of η Coronæ Borealis, takes the opportunity to determine the probable error that accompanies the observation of position angle and distance in the case of the better-known double star observers. Three stars have been selected for the discussion. η Coronæ, a close double, in which the probable errors are referred to a common distance of $0''\cdot7$; α Centauri, reduced to a mean distance of $10''$, and, of course, including a different class of observers; and γ Virginis, with a mean distance of $2''\cdot5$. Dr. Doberck might with advantage have given the aperture of the telescope with which the observations have been made, but a glance at the list is sufficient to show that the greatest accuracy, as might have been anticipated, is on the side of the large telescopes. In the case of η Coronæ, Profs. Hall and Burnham are the only observers whose probable errors fall below 1° in position angle. In distance, their only competitor is M. Perrotin, who also has the advantage of large aperture. With γ Virginis, where the components are more widely separated, telescopes of moderate size are able to compete advantageously, and the measures of MM. Duner and Schiaparelli appear quite as trustworthy as those of Prof. Hall. The probable errors attached to observations made in the southern hemisphere are, on the whole, slightly larger than those derived from northern observers.

VARIABLE STARS.—Owing to the rapid accumulation of new material, which seems to be coming in on all sides, Dr. Chandler thinks that a new edition of his catalogue, incorporating everything up to date, is necessary. With this we entirely agree with him; for, although the system of supplements is a good one, they *can* accumulate, and when this happens the sooner they can be eliminated the better. Our readers are so familiar with these catalogues, that little need be said when it is stated that Dr. Chandler has entirely overhauled the work, and brought in all the new material. It is good, however, to hear, as he says, that the "degree of uniformity and completeness of the observation of the phenomena, and the consequent development of our knowledge with regard thereto, during the past few years is remarkable." He adds, however, further that the need for volunteers in the southern hemisphere is pressing (*Astronomical Journal*, No. 379).

VARIABLE STAR OBSERVATIONS.—Profs. Barnard and Chandler have both called attention to possible errors introduced into the observation of variable stars from physiological causes. The latter thinks that a systematic error arising from unequal sensitiveness of different portions of the retina, dependent upon different positions of the variable star with reference to those with which it is compared at different hour angles, can be traced in the case of the minimum phase of U Pegasi. Mr. A. W. Roberts, in the *Astronomical Journal*, No. 381, urges the employment of some mechanical means for the elimination of this source of error. He himself has been in the habit of using both a negative and a direct-vision eyepiece, and taking the mean of the two observations. In this way, it is asserted, the mean error of observation has fallen from 0·12 mag. to about 0·05 mag. The obvious suggestion of employing a prism mounted behind the eyepiece, and taking four observations in such a manner that the comparison star is rotated 90° about the variable, is not lost sight of; and when this arrangement is carried into effect, it is confidently anticipated that the mean error will not be greater than 0·03 mag. It is needless to point out that this implies a greater degree of accuracy than has been attained with any photometer. The probable error in the case of the Harvard photometer has been quoted as 0·075 mag., and Drs. Müller and Kempf, with the Zöllner photometer at Potsdam, have not been able to make their probable error much below 0·06 mag. Mr. Roberts' experiment will, therefore, be watched with considerable interest.

THE CAPE OBSERVATORY.—The Observatory Report for 1895 furnishes several items of general interest. The fine equatorial, presented by Mr. McClean, is in an advanced state, the only part not yet commenced being the line-of-sight spectroscope. Besides the cylindrical observatory and hemispherical dome, the donor has generously provided a rising floor of excellent design, and also an attached building containing entrance hall, study, developing room, and instrument store. The objective prism of 24 inches aperture has been completed by Sir Howard Grubb. The chief part of the year has been occupied in clearing off arrears of reduction and publication. The publications during the year included—"The Cape General Catalogue for 1885, with Appendices, &c."; "A Determination of the Solar Parallax and the Mass of the Moon from Heliometer Observations of the Minor Planets Iris, Victoria, Sappho"; the first volume of the "Cape Photographic Durchmusterung," containing the mean places of 152,000 stars for 1875, derived from Cape photographs between Declinations −19° and −37°; a complete account of the "Geodetic Survey of South Africa." Much actual observational work has been entirely suspended to allow of these publications being completed. It is also mentioned that an increase of staff will be required for the new astrophysical department created by the advent of the McLean telescope. With the transit instrument 2872 stars have been observed, the small number being due to the objects being chiefly slow-moving circumpolar stars. The work with the astro-photographic telescope has been satisfactory. 91 catalogue plates were taken, 55 of these being finally passed. 367 chart plates were exposed, 240 being passed. This leaves 15 catalogue and 253 chart plates yet to be done to complete the complement assigned to the Cape. A complete investigation of the réseau used here (Gautier No. 8), has been made, and will soon be published. The observations made with the zenith telescope in 1892, 1893 and 1894, for aberration and change of latitude, are completely reduced, and are being finally revised.

AN INVESTIGATION ON ABERRATION AND ATMOSPHERIC REFRACTION.—The latest volume of the publications of the Washburn Observatory of the University of Wisconsin (vol. ix.) contains an investigation, by Mr. George C. Comstock, on "Aberration and Atmospheric Refraction." It may be remembered that M. Lœwy pointed out the extended use of the equatorial telescope and its adaptation to new lines of research through the introduction of reflecting surfaces in front of the objective. The method adopted here, however, deviates widely from Lœwy's, for reasons given by the author in the introduction. Instead of the employment of a prism in front of the object-glass (the fundamental idea of the apparatus designed by M. Lœwy), the reflecting surfaces of which were the silvered faces of an equiangular glass prism, Mr. Comstock substituted for it three plane mirrors of rectangular cross-section. By this means he was able to overcome the great drawback, met with when using the prism, of the deformations of the prism arising from changes of temperature, and producing errors of focus which seemed to be insuperable with this type of apparatus. A detailed description of the mirrors and method of mounting, too long to be referred to here, is given. Mr. Comstock next enters on the determinations of the errors of the apparatus, and gives tables of the instrumental constants that follow, a description and investigation of the micrometer employed, and the effect of aberration and refraction upon the apparent distance between two stars respectively. Several other points are investigated, which he found were important after a preliminary trial of the method he adopted. From the discussion of 822 observations of the angular distances separating thirty-nine pairs of stars made by two observers, it appeared, as he says, "that the apparatus as employed is capable of furnishing a very considerable degree of precision, the probable error of a single observation made under normal conditions being $\pm\ 0''\cdot30$, *i.e.* less than a millionth part of the quantity measured." As mentioned before, the observations were made to determine, from the annual variations

in the distance separating each pair of stars, a value of the constant of aberration, and a second part of the work was to make a comparison of the measured and computed distances, which would give the corrections to be applied to the refraction tables. A series of subsidiary investigations, the results of which are given on page 203, was also completed. The result of the whole investigation furnishes as a definite result: Constant of Aberration $= 20''\cdot443 \pm 0''\cdot010$, which differs only very slightly from the commonly accepted value obtained by Struve, and this within its own limit of probable error. The volume is accompanied by some excellent illustrations of the instrument and the novel dome which protects it. The second part of this volume contains the observations of the right ascensions of the stars observed with the prism apparatus made by Mr. Albert S. Flint.

NEW FEATURE ON MARS.—A telegram from Kiel announces the observation of a bright prominence on the terminator of the planet, by Messrs. Hussey and Holden, at the Lick Observatory on Wednesday last, August 27. The planet is well situated for observation at midnight, being at present some five or six degrees north of α Tauri.

THE ECLIPSE AT BODÖ AND NORTH FINLAND.

WE give this week a reproduction of the drawing of the corona made near Bodö, which accompanied Dr. Brester's letter in our last issue (p. 390).

Further particulars have been received concerning the doings of the Russian Expedition under Baron Kaulbars, which observed in Russian Finland. There was an unusually large development of the corona, the extensive and often oblique rays of which surrounded the dark disc of the moon. One of these rays reached a length double that of the sun's diameter. Some of the rays crossed each other, and Baron Kaulbars writes to the *St. Petersburger Zeitung* "that the remarkable proportions of the corona coincide with the opinion according to which this phenomenon is only very little developed with a *minimum* of sun-spots, for he had been able to see only very insignificant spots on the sun at rare moments during observations extending over several weeks."

Dr. Brester's drawing of the Corona.

Other expeditions to the Maritime Province of the Amur appear to have been very successful.

ON THE RÖNTGEN RAYS.[1]

WHO would have dreamt at the last annual meeting of the Victoria Institute, that before a year was out, we should be able to see on a screen, to receive on a photographic plate, which is afterwards developed, the skeleton, or a portion of the skeleton of a living man, or at least a living child? And as the modes of exciting these rays improve, we shall probably go on, step by step—indeed already, I believe, the whole body of a full grown man has been penetrated by these rays, the discovery of which we owe to Dr. Röntgen.

I feel some diffidence in bringing this subject before you, because I have never, myself, made experiments with the Röntgen rays. Nevertheless I have read a good deal about them, following what others have done, more especially where it connected itself with the subject of light, to which I have paid a good deal of attention. So I cannot but have a tolerably definite idea in my own mind as to the nature of these Röntgen rays which has been a matter in dispute and, I may say, is still in dispute, although I think opinions are generally coming round to that which I will bring before you in the end.

Now before I go to the Röntgen rays direct, I must touch on previous work which gradually led up to them.

For a very long time it has been known that an electric discharge passes more readily through tolerably rarefied air, than through air of greater density, and so with other gases. If we have a longish closed tube, provided with electrodes at the ends by means of platinum wires passing through the glass, if the air be tolerably exhausted from it, an electric discharge passes, comparatively speaking, freely through it, forming a beautiful skein of light, if I may so speak, and under certain circumstances that skein of light is divided into strata in a very remarkable manner. These strata fill the greater part of the tube from the positive electrode, or anode, as it is called, till we get nearly, but not quite, to the negative electrode, or kathode. There is a dark space separating the end of the positive discharge which, as I said, under suitable conditions and sufficiently high exhaustion, shows stratification, from a blue glow enveloping the negative electrode or part of it. The luminosity about the kathode is somewhat indefinitely bounded on the side of the stratification.

When, however, the exhaustion is carried still further, at the same time the strata become wider apart, and the luminosity recedes from the kathode and expands, forming a sort of glowing halo much more sharply defined on the inside than the outside; in that respect resembling the ordinary luminous halo—not the corona—occasionally seen round the moon. We have here, then, these two dark spaces, one outside the halo, where the luminosity gradually fades off, and another dark space on the inside, where the luminosity is more sharply defined, and which reaches to the negative electrode.

Now it is the phenomena in connection with this second dark space that I have more particularly to bring before you. As the exhaustion is rendered higher and higher, the inner dark space gets wider and wider until at a sufficiently high exhaustion it fills the whole tube or bulb. Mr. Crookes has worked more especially at this subject, and, indeed, the tubes which are now used for the production of the Röntgen rays, are generally called "Crookes tubes." I have seen in some of the foreign periodicals the word "Crookes" used to signify one of these tubes. Mr. Crookes' researches in very high vacua led him up to that most remarkable instrument, the radiometer, the nature of which led us to form clearer conceptions, than we had hitherto done, of the nature of the motion of molecules in gas; or rather, when the theory of the radiometer was made out, presented us, as I may say, with a visible exhibition of the thing in actual working.

Now these researches, which led Mr. Crookes to improve his vacuum, naturally led him to examine the electrical phenomena produced by excessively high vacua.

I have said that it was with the second or inner dark space that I had chiefly to do. When the exhaustion is sufficient, that fills the whole tube.

Now what takes place in this dark space? Suppose we interpose a screen, such as a plate of mica with a hole in it. A portion of the discharge from the negative electrode goes through that hole and continues onwards in a straight course until it reaches the wall of the tube. When it reaches the wall

[1] An extract from the Annual Address to the Victoria Institute, by Sir G. G. Stokes, F.R.S., the President.

of the tube (I will suppose the tube, as it is called, to be made of German glass) it produces a greenish yellow fluorescence, or phosphorescence of very brief duration. I need hardly say that if you do not limit what comes from the negative electrode by the screen with a hole in it, you get a broader beam which affects the glass wall over a larger space.

Now what is it that proceeds from the negative electrode towards the glass, and, when it gets there, produces this phosphorescence? Is it light, or is it matter?

One remarkable circumstance connected with this *something* is, that you can deflect it in its course by a magnet. If you present a magnet to a ray of light it does not deflect it at all; but this *something* is easily deflected by a magnet, even by a tolerably weak magnet. Mr. Crookes found that in addition to that property, if this discharge of a something fell upon one side of a very light fan, formed of thin, split mica, and delicately mounted so as to enable it to spin readily, it sent it spinning round; and he believed that the nature of that which we have here to do with is, that it is a stream of molecules. Nobody, I suppose, denies that there is matter propelled; but there has been a considerable difference of opinion as to whether the matter propelled is of the essence of the phenomenon, or whether it is something merely accidental. Mr. Crookes held that it was of the essence of the phenomenon, and that we had here, really, a stream of molecules, and I must say, for my own part, I believe he was right. But some foreign men of science hold that the projection of matter is altogether a secondary phenomenon, and that what comes through this small hole is really only a process which goes on in the ether—something so far of the nature of light, but yet differing from ordinary light most markedly in the property of being deflected by a magnet. To illustrate what I mean by saying something secondary, Prof. Wiedemann, who holds the opinion that it is of the nature of light, or a process going on in the ether, imagines that the projection of matter has no more to do with the phenomenon than the path of a cannon ball has to do with your hearing the sound of the cannon. I think, myself, that it has a great deal more to do with it than that. However, I will leave that matter for the present, to pass on to some researches which led up to the remarkable discovery by Dr. Röntgen.

In Germany, Prof. Lenard made a very remarkable series of experiments in what the Germans call, and what we may call, the kathodic rays, and which he believed to be actual rays, and not streams of molecules sent from the kathode. In order to produce these rays, as I will call them, you want a very high vacuum. If, however, you make your vacuum too high and too nearly perfect, you cannot get the electric discharge to pass through it. A perfect vacuum appears to be a non-conductor, and if you attempted to make the electric discharge pass through it, it would go, by preference, on the outside from one electrode to the other, so that you cannot work directly with anything too nearly approaching to a perfect vacuum. But it is a very remarkable thing, though Lenard, I believe, was not the first to discover it, but Hittorff, that these kathodic rays pass or appear to pass through a plate of aluminium which is perfectly impervious to light, or even to the ultra-violet rays, which we know by their effects, though we do not see them directly; so that you may have these kathodic rays at one side and something of the same kind at the other. Lenard constructed an apparatus commencing with a Crookes tube, in which there was very high, though not too high, exhaustion, with a kathode which was either flat or cup-shaped at one end, and opposite to that, in the part where the kathodic rays would strike the glass if it were there, instead of glass it was closed by a thin plate of aluminium foil, so thin that it would support the atmospheric pressure although it was impervious to air. But as a continuation of that tube he had another tube, which was also capable of exhaustion. The two tubes had glass tubes leading from them to the same air-pump. There was communication with the air-pump and communication between the two tubes, and you could exhaust them together, and the pressure would be so far reduced that the aluminium plate was strong enough to sustain the reduced pressure. They were both exhausted together until a suitable exhaustion was produced for the production of the kathodic rays in the first tube, and then the connection between the two tubes was intercepted, and the exhaustion of the second tube, which was kept connected with the air-pump, was continued for several days, until, as near as he could get it, there was nothing at all, in the way of gas, left in it. What was the result? In the first tube the kathodic rays were produced by the electric discharge. They fell on the aluminium foil at the end, and then there was a continuation of kathodic rays in the highly exhausted tube—the vacuum tube I will call it—and these went on as if they had been rays of light. They were deflected by the magnet just like the original kathodic rays.

Now at first sight that looks very much as if you had to deal with actual rays, which passed through the aluminium foil, just as rays of light would pass through a plate of glass. But I think the real explanation of it is altogether different. I believe it to be of this nature. First I will use rather a gross illustration, in order that you may the better apprehend the nature of the other explanation that I am about to bring before you. Suppose that I have a row of ivory balls in contact, such as billiard balls, and that another similar ball strikes the first of these. The result is that the last of the balls is sent off, and the striking ball and the intermediate balls remain approximately at rest. Now it is conceivable that something analogous to that may take place as regards these so-called kathodic rays, supposing they are not rays at all, but streams of molecules. It is conceivable that the molecules proceeding from the kathode or negative electrode of the first tube, be they of residual gas, or aluminium, or platinum, might fall upon the thin aluminium plate which forms a wall between the two tubes, separating the one from the other, and that that would give rise to molecular discharge in the second space, although the actual moving molecules never passed through the wall. As I say that is a rough illustration—rather a gross and material illustration—to enable you to understand more clearly the view I have to bring before you.

I have said that the so-called kathodic rays are easily deflected by a magnet. Now we know from other experiments that if a body sufficiently charged with electricity is in rapid motion, and that motion takes place in a magnetic field, the body tends to be deflected. This looks, therefore, very much as if these kathodic rays are actually streams of molecules, which being highly charged electrically, and of almost inconceivable minuteness, would be deflected by a slight magnetic force. Now, if these highly-charged molecules come to strike on the aluminium wall which separates the two tubes (which are end to end) from one another, it may be that an electrical action goes on which resembles very much what electrolysis is supposed to be according to the views of Grotthuss. I shall not have time to enter into an explanation of that now, for it would lead me too far from the subject; but several present will no doubt understand what I mean when I refer to the views of Grotthuss. The molecules then impinge on the wall, and give rise to a projection of molecules from the second side of the wall, but the latter are not the same molecules which impinged on the first side of it. Whether the molecules projected in the second tube come from a very minute quantity of residual gas, or whether they are derived from the aluminium wall itself, from which they are torn, as it were, does not signify for my purpose. We have here, you see, a conceivable mode of emitting these so-called rays in this way, simulating the transmission of a ray of light through a plate of glass, though it is no ray at all that we are dealing with. I confess I think that that is the true view of the action which takes place. But Lenard himself believed that the kathodic rays were, as he said, processes in the ether. By means of the first tube used alone, as was done in the first instance, but closed with a "window" of somewhat thicker aluminium foil, so as to sustain the atmospheric pressure, he was able to receive the kathodic rays which came from the second surface of the aluminium foil in air, where he could examine them at pleasure, using for their detection sometimes a phosphorescent or fluorescent screen, sometimes a photographic plate. He found that under these conditions they were quickly deflected from their original direction and dispersed, so that they could not be traced far, just like rays of light in a turbid medium, such as water to which a little milk has been added; whereas in a subsequent series of experiments, to which reference has already been made, in which the kathodic rays were received into a second tube, the dispersion became less and less as the exhaustion proceeded, until at the highest attainable approach to a perfect vacuum the dispersion almost disappeared, and the rays were traced right onwards for a metre and more, and that, without being enlarged by diffraction, as would be the case with rays of light.

Lenard mentioned incidentally that these kathodic rays, as he supposed they were, were able to pass through the hand even. He missed the discovery of the X rays because he had,

I may say, the kathodic rays too much in his head, and attributed the whole effect on either side of the wall to the kathodic rays. Really the effect is due in part to the kathodic rays, and in part to the Röntgen rays, the existence of which he was not aware of. They cannot be distinguished merely by their effect on a fluorescent screen or on a photographic plate, since both these recipients are affected by the rays of both kinds.

Such was the state of things when Röntgen made his remarkable discovery. According to an account which I saw in one of the newspapers (we cannot vouch for the truth of everything we see in the newspapers), the discovery was made in the first instance accidentally. I cannot give you more authentic information than that, but he had been working with a Crookes tube and he observed that a photographic plate, enclosed in the usual case in which these plates are enclosed when you want to protect them from light, showed on development certain markings an it ; so he put the whole apparatus as it had been, with a photographic plate in its case in the same position as before, and the thing was repeated. That is according to the account in the newspapers. A very remarkable discovery was the result. He found that rays were capable of coming out of some part of a Crookes tube which had the remarkable property of passing through substances that are opaque to ordinary light, and opaque even to the ultra-violet with which we were previously acquainted. They pass freely through black paper, through cork, wood, or even through the flesh of the hand, though less freely through the bones, so that by simply laying his hand upon the case containing the photographic plate, he actually got a photograph of the bones of his hand.

Well, what is the nature of these rays and from whence do they come? As Röntgen said in his original paper, a slight examination shows that they have their origin in the part of the Crookes tube opposite to the kathode, and which is rendered phosphorescent by the discharge from the kathode.

The rays, however, which come from this part of the tube, and which appear to have their origin there, differ utterly in some respects from the so-called kathodic rays. If you isolate a portion of them, you find that a magnet has no action upon them ; unlike the kathodic rays, they proceed onwards without deflection, just as if the magnet were not there. Like light they proceed in a straight course, but these rays are able to pass through a variety of substances that are opaque to ordinary light, while on the other hand they are stopped by other substances which let light freely through. That, however, does not prove that they are not of the nature of light. You may have, suppose, a red glass which is opaque to green rays, but lets red rays through very freely, so that as regards merely the fact of the X rays being stopped by substances transparent to light, while they pass more or less freely through other substances which are quite opaque to ordinary light, that establishes no greater distinction than exists between green and red light. Are they then of the same nature as light?

The X rays have some very remarkable properties by which they appear at first sight to differ *in toto* from ordinary light. They pass with either no refraction, or excessively small refraction, through prism-shaped bodies, which we know rays of light do not. They suffer hardly any, if any, regular reflection, unless perhaps at a grazing incidence.

Röntgen himself, in his original paper, dwelt on these peculiarities of the new rays. He formed a prism of aluminium, with which he attempted to obtain deviation of the new rays, but the experiment showed that if there were any deviation at all, at any rate the refractive index could not exceed 1·05. He speaks of the rays not being apparently capable of regular reflection, but he brought forward experiments which show that in a certain sense they appear to be capable of reflection.

A photographic plate with the sensitive surface downwards was placed in its case under a Crookes tube, and immediately under the plate, and inside the case, were placed portions of different kinds of metal, which would be capable of reflecting back the rays on to the sensitive surface, if they admitted of reflection ; and it was found that the plate was much more darkened over certain of those metals than where the metal did not exist. There was very little darkening over aluminium, and a great deal of darkening comparatively over platinum. This indicated that some effect was produced, though the greater part of it is not one of regular reflection. He conceived the effect to be one of reflection such as you might have from a turbid medium.

There is, however, another mode of explanation which seems worth considering, viz. that the Röntgen rays, falling upon the metal, throw the molecules into a state of vibration, which they communicate to the ether, by a sort of phosphorescence or fluorescence of X light ; so that the rays which come from the molecules, though perhaps not of exactly the same nature as the X rays that fell upon them, still have enough of the "X" quality about them, whatever that is, to enable them to get through objects which are opaque to ordinary light.

Lord Blythswood, who has worked a great deal with the Röntgen rays, has written a paper, which was communicated to the Royal Society by Lord Kelvin, in which he establishes a minute regular reflection of those rays from speculum metal at an angle of about 45°. Two plane specula were placed side by side so as to receive at that angle the X rays coming from a Crookes tube, and a duly protected photographic plate was placed in such a position as to receive the regularly reflected rays if there should be any. The developed plate appeared to show a slight indication of the junction between the mirrors ; and that the appearance was not illusory was shown by Lord Kelvin, who made measurements on the image and compared the results with what they ought to be on the supposition of a regular reflection. The indication was so faint that I could not myself perceive it (I have not seen the negative, but only positive copies), but Lord Blythswood has given me some positive copies of a negative which he subsequently obtained by reflection from a concave speculum at a small angle of incidence, and which show for certain a minute regular reflection of X rays, while at the same time they prove that the quantity of X light returned by regular reflection is extremely small compared with that which comes from the mirror by some different process.

Now there is another remarkable property of these rays, or absence of property, if you like so to call it. Rays of light, as we know, admit of diffraction. If you pass light from a luminous point through a very small slit, or a small hole, the riband, or the beam of light at the other side, does not follow merely the geometrical projection of the slit or hole as seen from the source of light, but is more or less widened, and certain alternations of illumination are visible, a phenomenon referable to interferences which I have not time to go into. How do these X rays behave under such conditions? It is a very remarkable thing that they do not show these enlargements or exhibit any sign of interference.

The last number of the *Comptes rendus* contains a paper by M. Gouy in continuation of a former paper, but describing experiments carried out in a still more elaborate manner, which proves the truth of this to a very high degree of strictness. He makes out that if these X rays are periodical, the wave-length cannot well be more than the one-hundredth part of the wave-length of green light, indicating an enormously high degree of frequency.

Now, if we assume that the X rays, like rays of light, and unlike the kathodic rays, are a disturbance propagated in the ether, ponderable matter being concerned only in their origination, not in their propagation, the question arises, What is the relation between the direction of vibration and the direction of propagation? Are the vibrations normal or transversal? We know that the vibrations of the air which constitute sound take place in a to and fro direction, or are what is called normal—that is, perpendicular to the waves of sound. We have the fullest evidence that the vibrations of the ether which constitute light take place in directions perpendicular to that of propagation, or are what is called transversal. To which category do the vibrations belong which constitute the X rays?

If we could obtain polarisation, or even partial polarisation, of the X rays, that would settle the question, and prove that they are due to transversal vibrations. But most of those who have attempted to obtain indications of their polarisation have failed. This, however, does not prove that the vibrations are normal, for the peculiar properties of the X rays shut us out—or, at least, almost completely shut us out—from the ordinary means of obtaining polarisation. There is, however, one paper in the *Comptes rendus*, by Prince Galitzine and M. de Karnojitsky, in which the authors profess to have obtained by a special method undoubted indications of polarisation. No reasonable doubt can remain as to the abstract capacity of these rays for polarisation after what has been done by another physicist. I wish I had time to go into the experiments that

have been made by M. H. Becquerel in the direction of polarisation; but I have already kept you too long. He had more particularly studied a very remarkable phenomenon, viz. that certain phosphorescent bodies—such as sulphide of calcium, for instance, and salts of uranium—on exposure to ordinary sunlight give out rays of some kind which pass through bodies opaque to light, and are able to affect a photographic plate beneath them. So far these agree in their properties with the X rays which are obtained from a Crookes tube, which they far more closely resemble than they do rays of ordinary light; but the rays thus obtained were found by Becquerel to admit of polarisation by means of tourmalines in a manner altogether unmistakable. I think, therefore, that we may take it as established that the Röntgen rays are due to some kind of transversal disturbance propagated in the ether.

The non-exhibition of the ordinary phenomena of diffraction and interference is explicable on the supposition that the vibrations in the X rays are of an excessively high order of frequency. I am not sure that a different sort of explanation might not, perhaps, be possible which I have in my mind, though I have not matured it; but, save the possibility of that, one is led to regard them as consisting of transverse vibrations of excessively high frequency. This opens out some points of considerable interest in the theory of light; but I am afraid it would keep you too long if I were to attempt to go further into this matter. I will merely remark that, taking the way in which these rays are most commonly produced, viz. as coming from a point where the kathodic discharge in the Crookes tube falls on the opposite wall, we may understand how it is that vibrations of excessively unusual frequency may be produced. These highly charged molecules, charged with electricity, coming suddenly against the wall, may produce vibrations of a degree of frequency which we are not at all prepared for; but I see by the clock that I must not detain you any longer on speculations.

Postscript.—This "different sort of explanation" is one between which and the supposition of periodic vibrations of excessively high frequency my mind has for a long time oscillated. In the above lecture I gave the preference to the latter; but subsequent reflection leads me strongly to incline to the former. I hope before long to develop fully these views elsewhere; meanwhile, suffice it to say that I am disposed to regard the disturbance as non-periodic, though having certain features in common with a periodic disturbance of excessively high frequency.

THE ICE VOYAGE OF THE "FRAM."

DR. NANSEN has communicated to the *Daily Chronicle*, by telegraph from Tromsö, some interesting details given by Captain Sverdrup, with reference to his voyage in the *Fram*. The marvellous way in which the *Fram* withstood the ice-pressure, and the methods employed to free the ship from the ice, is an object-lesson for future Arctic explorers. The telegram is abridged below.

On March 14, 1895, Nansen and Johansen left us. During the first month after their departure, the ice was very quiet and the drift inconsiderable. Towards the end of April the drift, however, improved, and we were carried westwards. On July 26 the *Fram* was in 84° 50′ N., and 73° E. long. There was during this time much ice-pressure, but it never reached the ship. Then we had winds from south-west and west, which during the summer drifted the *Fram* backwards towards the east and north-east. It was not before October that the favourable drift recommenced, and during the autumn and winter, and especially during January and the first part of February 1896, our drift was better than ever.

On October 16, 1895, the *Fram* had reached the highest latitude observed, viz. 85° 57′ N., and 66° E. long. In the middle of February we were on 84° 20′ N., and 23° E., but here the drift closed until May, when we were again carried southwards. On July 19 we had reached 83° 14′ N., and 14° E. long.

There we got the *Fram* out of the grasp of the ice by blasting with gun-cotton and powder, and began to force our way southwards. During the whole drift in the ice the *Fram* was exposed to constant and violent pressures. None of these were, however, so dangerous as that which we had at New Year before Nansen left us. Immediately after his departure we were occupied in removing the huge mass of ice which on that occasion was pressed against the *Fram's* sides. At the end of March, just as the last portion of this ice was being removed, the ice suddenly cracked in all directions round the ship, and a broad water-lane was formed, which came within a few feet of the *Fram's* stern. Strong pressure very soon began along this crack, and the ice was so much broken up that the *Fram* at the end of July lay close to open water. A single mine was sufficient to free the ship from the ice.

As this mine was exploded, the *Fram* glided from the ice into the water like a ship being launched from her ways, but with a noise like thunder, the crew cheering loudly as she struck the water. Having been brought into a safe harbour by warping and sawing the ice, she was again, in August, frozen in. The ice-pressures were, during this year, of no great importance in comparison with the pressures this last summer.

During one week in June this summer (1896), at the height of the spring tides, the *Fram* was regularly exposed to violent pressures caused by the changing tide-currents. She was then once or twice a day lifted 6 to 9 feet, and her bottom could be seen resting on the ice. On all these occasions the *Fram* proved to be the very ship for ice. She was quietly lifted, and not a noise or a crack was heard from her timbers. The men on board were not disturbed in their slumber, even when the pressure was at its highest, and we awoke in the morning in ignorance of what had happened during the night. It was not before we came on deck that we observed how high we were lifted above the ice.

The temperature of the air was pretty even during our whole voyage, and did not fall lower than during the first winter. The depth of the sea was during our drift about the same as we had found before Nansen's departure, viz. 1800 to 1900 fathoms. In the temperature of the sea there was also little change, but the warm layer of Gulf Stream water under the cold surface-water increased a little in body as we came westwards. Depôts of provisions, boats, kayaks, and all necessary equipment were during our whole drift kept in readiness on the ice in the neighbourhood of the *Fram*, in case of fire or other accidents.

The time passed comfortably and peacefully, much in the same way as during the first winters. An easier expedition can hardly be imagined. Our principal work was to take the regular observations, sleep, eat, and drink. Our health was perfect the whole time, and we had no sign of scurvy. When the ice began to slack a little this summer, we worked hard to loosen the *Fram* from the ice—a difficult task, owing to the huge ice, piled up by pressures, in which our ship was frozen. We succeeded, after some days' hard work, by blasting, using mines of up to 100 lb. of powder. Guncotton proved the best.

From July 19 to August 13 we forced our way southwards through 150 miles of close ice. The ice was, as a rule, very high, and the floes were so extensive that we could not see all of them, even with telescopes. It often seemed to be hopeless, and if the *Fram* had not been such a superior ship for ice-navigation it would have been quite useless to try to force our way through ice-masses of such a description. It was by steam and warping that we broke our way through foot by foot, and where the ice was too bad for this it was forced by blasting.

We came out of the ice on August 13—the same day on which Nansen and Johansen arrived at Vardö in Norway.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Lords of the Committee of Council on Education have appointed Mr. A. J. R. Trendell, C.M.G., to be Assistant-Secretary of the Department of Science and Art, in succession to Mr. G. F. Duncombe, retired. Mr. Edward Belshaw succeeds Mr. Trendell as the Chief Clerk.

THE retirement of Prof. Erismann from the chair of Hygiene in the University of Moscow, is announced.

COLONEL PENNYCUICK, late R.E., has been appointed President of the Engineering College, Cooper's Hill, in the place of General Sir Alexander Taylor, retired.

THE following announcements have been recently made:—Dr. Burney Yeo, to be Professor of Medicine, and Dr. Curnow, to be Professor of Clinical Medicine at King's College, London.

A SCHEME for a Central Technical College in Liverpool, for which the plans have already been accepted, now awaits the

sanction of the City Council. The estimated cost, apart from the final equipment, amounts to £80,000.

THE syllabus of lectures at the British Institute of Preventive Medicine, for the Session 1896-97, has just been issued, and contains particulars as to the work in the following departments:—Bacteriology: (1) Bacteriology in relation to Medicine and Pathology; (2) Bacteriology in relation to Hygiene; (3) Biological Chemistry; (4) Original Research Work: Hygiene, Clinical Investigation, Bacteriology of Fermentation, Water Laboratory, and Photomicrography.

THE following appointments have recently been made at the Swansea Technical School:—Lecturer in Metallurgy, Allan Gibb, Honours Associate in Metallurgy of the Royal College of Science. Lecturer in Physics, W. Williams, B.Sc. (London), Senior Demonstrator, Physical Department, Royal College of Science. Lecturer in Engineering, T. Gilbert Jones, B.Sc. (Vict.), Wh.Sc., &c., Lecturer in Applied Mechanics and Steam, Huddersfield Technical School.

AMONG recent appointments abroad we notice the following:—Prof. Thomas A. Williams, of South Dakota, to be Assistant in the Division of Agrostology of the Department of Agriculture; Mr. F. S. Earle, to be Professor of Biology at the Alabama Polytechnic Institute; Dr. Karl Rümker, to be full Professor of Agriculture in the University of Breslau; Dr. F. W. Küster, to be Professor of Physical Chemistry in the University of Göttingen; Dr. Wm. Sandmeyer, to be Professor of Physiology in the University of Marburg; Dr. Max Fischer, to be Professor at the Agricultural Institute at Leipzig; Dr. Richard Lorenz, to be Professor of Electro-chemistry at the Polytechnic Institute at Zürich; Herr Troske, to be Professor of Engineering at the Technical High School, Hanover; Dr. J. Biehringer, to be Docent in General and Technical Chemistry at the Technical High School, Braunschweig; Dr. Benecke, to be Docent in Botany in the University of Strasburg.

THE *Calendar* of the People's Palace, East London, Technical College for the Session 1896-7, contains information concerning all the classes which are to be held next winter, and their name seems to be legion. Not only can the student of pure science receive instruction in any branch from thoroughly competent teachers, but also the person desirous of help in learning how to make artificial flowers for bonnets, or how to cut out a coat. We fancy it would be difficult to name a subject which does not come within the syllabus of this technical school. We refer the students of East London to the *Calendar* itself for information concerning scholarships, exhibitions, fees, &c.

THE City of London College, Moorfields, has issued its list of classes to be held during the forthcoming session, and a very full syllabus of lectures proposed to be given in the Engineering Laboratory of the same establishment has reached us.

PARTICULARS of the technical instruction lectures and classes organised by the British Horological Institute, Northampton Square, London, E.C., have been published for the session, which commences on September 8. They include drawing and theory classes held at the Institute on Tuesday and Thursday evenings, or instruction in theory by correspondence. Ordinary and honours theory examinations, held at the end of April in each year, are opened to all engaged in the horological trades. Certificates are issued to watch and clock repairers who satisfy the examiners of their proficiency. The certificates will be of two classes, both for watches and clocks: an ordinary and an honours certificate. Practical examinations in new work will be held annually in April, and the silver medal of the Institute will be awarded to recipients of the honours theory certificate and the practical certificate for new work, who obtain the largest aggregate number of marks in both examinations.

THE Aberdeen County Council, says *Education*, is making careful inquiry at various fishing centres as to the extent to which the County Councils in England have provided technical instruction for fishermen. The Cornwall County Council spends between £500 and £600 per annum on this branch of their work, and they have appointed a lecturer to give instruction on the curing of herring and pilchards; the natural history of crabs and lobsters, mackerel, oysters, and salmon; the making of crab-pots, splicing and net repairing, and so on; and to supervise demonstrations on oyster and lobster culture at Falmouth. Instruction is also provided in the subject of navigation, with a view to the examinations of the Board of Trade. The Essex County Council have started a marine biological station at Brightlingsea, to give practical instruction in the natural history of food fishes and other creatures. Experiments are also conducted in oyster culture, and lectures and demonstrations are given at the station. In Lancashire and Northumberland instruction has been given on the natural history of fish and navigation. At the conference, which was held last December, the proposal was put forward that a few practical fishermen should be selected from different centres in Aberdeenshire, and enabled to visit the more important fishing centres with a view to acquiring, and afterwards extending, a knowledge of the different methods of fishing, the treatment of fish after capture, preservation, and so on.

THE Department of Science and Art has issued the following lists of Scholarships and Exhibitions just awarded:—Whitworth Scholarships (tenable for three years), £125 a year each: Frederick C. Lea (24), engineer; William A. Taylor (23), engineer; Henry T. Davidge (24), engineer; John W. Hinchley (25), student (formerly engineer). Whitworth Exhibitions (tenable for one year), £50 each: William Du Bois Duddell (23), engineering student; John A. Sloan (23), engineer; Alfred J. White (20), engine-fitter apprentice; Hugh Wallace (21), engineering student; Edward A. Gere (22), student; Frank W. Arnold (23), engineering teacher; Hugh B. Phillimore (22), electrical engineer; Hanson Topham (19), mechanic; Harry E. Wimperis (19), engineer; Charles E. Handy (19), engine-fitter apprentice; Bertram J. Rouse (22), engine fitter; Frank H. Corson (19), fitter apprentice; Thomas G. Procter (20), engineering student; Harry Geldart (21), mechanic; Hector H. Garratt (20), engineer apprentice; George Wall (22), engineering student; George W. Howe (20), electrical engineer apprentice; William W. Firth (21), engineering student; Harry Grute (22), fitter; Hugh J. Williams (23), turner; Frank Mould (24), engine fitter; Frank H. Jeffree (22), engineer; Denys Walton (19), engineer apprentice; Allan J. Grant (20), engineer; William G. Hibbins (24), engineer; Joseph P. Ward (21), engineer; George L. Overton (21), student; Asa Binns (22), fitter; Albert Pidgen (23), fitter; William P. Ferguson (21), fitter.

THE list of successful candidates for Royal Exhibitions, National Scholarships, and Free Studentships (Science) is as follows:—National Scholarships for Mechanics: Ernest Larmuth (17), student; Raymond B. Smith (17), engineering student; John B. Shaw (22), engineer; Frederick J. Tyler (22), engineer apprentice. National Scholarships for Chemistry and Physics: Henry L. Heathcote (19), student; James M. McEwen (17), solicitor's clerk; Arthur Hopwood (21), hatter; Percy Hughes (18), laboratory assistant; Sydney W. Smith (18), student. National Scholarships for Biological Subjects: Herbert Wright (21), weaver; Wilfred Thomas (20), laboratory assistant. National Scholarships: Alfred J. White (20), engine-fitter apprentice; James Walker (23), engineer; John Cresswell (19), student; Ernest W. J. Edwards (17), assistant demonstrator of physics; Archie McDougall (17), laboratory assistant; Frank E. Smith (19), laboratory assistant; George J. Fenwick (17), scholar; Hugh McDougall (19), laboratory assistant; Frank W. Arnold (23), engineering science teacher; Hanson Topham (19), mechanic; Harry E. Wimperis (19), engineer. Royal Exhibitions: William Alexander (20), engineer apprentice; William Scholes (16), student; Thomas G. Madgwick (18), engineering student; William Robertson (19), laboratory assistant; Charles E. Handy (19), engine-fitter apprentice; William Pickering (22), stonemason; George A. Robertson (22), engineering student. Free Studentships: Frank Jowett (18), student; Percy Kenyon (17), student; George W. Howe (20), electrical engineer apprentice; Frank Mould (24), engine-fitter; Philip G. Gundry (18), student; Allan Macdiarmid (22), student.

SCIENTIFIC SERIAL.

American Journal of Mathematics, vol. xviii. No. 3. (Baltimore, July.)—On the multiplication and involution of semi-convergent series, by Prof. Cajori. In vol. xv. Prof. Cajori has generalised Voss's results (*Math. Ann.*, vol. xxiv. p. 42), and some further contributions of his to this difficult subject are given in the *Bulletin* of the Am. Math. Soc. (vol. i. pp. 180–183). The search, he

remarks, for expeditious tests on the applicability of Cauchy's multiplication rule to powers of semi-convergent series higher than the second power, has given rise to the present investigation, which begins with alternating semi-convergent series, and ends with certain trigonometric series.—Analytic functions suitable to represent substitutions, is an interesting following-up of a theorem due to Hermite (*Comptes rendus*, vol. lvii. p. 750), by L. E. Dickson. Further generalisations are promised in a dissertation by the author.—S. Kantor contributes an elaborate memoir, "Theorie der Transformationen im R_r, welche sich aus quadratischen zusammensetzen lassen," which has as heading, "Boldness is caution in these circumstances."—Tactical Memoranda, i.-iii., by E. H. Moore, is the opening one of a series of papers which the author proposes to publish, on certain more or less closely connected topics of tactic. He starts from Cayley's division of algebra into tactic and logistic. This instalment bears upon the work of Reze (Geometrie der Lage), S. Kantor, Klein, and many others; it also gives a generalisation of the *fifteen-schoolgirls* arrangement, and considers whist tournament arrangements, which are in ultimate formulation purely tactical.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 17.—M. Marey in the chair.—On the copper mines of Sinai, worked by the ancient Egyptians, by M. Berthelot. These mines are near the coast of the Gulf of Suez, and are undoubtedly the most ancient known to history, having been worked at least 5000 years before the Christian era. They were abandoned about 3000 years ago, on account of the small amount of copper present in the ores. The reduction appears to have been carried out by methods not differing essentially from those in use at the present day, wood being used as the reducing agent, together with fusible silicates.—On the subject of a preceding communication, relating to some properties of primitive roots and secondary roots of prime numbers, by M. de Jonquières.—On an apparatus for aërial navigation, by M. Honoré.—Abstract of solar observations made at the Royal Observatory of the Roman College during the first half of 1896, by M. P. Tacchini.—Combination of argon with water, by M. P. Villard. When argon is compressed to 150 atmospheres in the presence of water cooled to 0°, local cooling at a point in the tube causes the separation of crystals, probably a hydrate, the dissociation tension of which at 0° is 105 atmospheres. Nitrogen and oxygen also combine with water under similar conditions, but at much higher pressures.—On the reticular structure of central nervous cells, by Mdlle. Wanda Sczawinska.—Contribution to the study of the coagulation of the blood, by MM. J. Athanasiu and J. Carvallo. It is concluded that in the normal state the blood and lymph contain elements, perhaps leucocytes, which supply the fibrin ferment necessary for the coagulation of these liquids, and that when these elements are prevented by any means, such as peptone, from fulfilling this function, the tissues are capable of replacing them.—Influence of certain substances upon the bactericidal properties of the blood, by M. London. The bactericidal power of the blood is markedly reduced by want of food, but increased by small repeated doses of sodium bicarbonate.—On the extraordinary refractions observed in the neighbourhood of lakes, and known under the name of *Fata Morgana*, by M. André Delebecque. The apparent enlargement of objects on the opposite bank of the lake is really due to the superposition of a number of images which, although not distinguishable by the unaided eye, are clearly separable by the aid of a telescope.—On the resolution of the general equation of the fifth degree, by M. L. Mirinny.

August 24.—M. A. Cornu in the chair.—M. Tisserand gave an account of the results of the observations made of the total eclipse of August 9. The results obtained by M. Deslandres at Yeso, and by Mdlle. Klumpke, at Vadsö, were unfavourable, but M. Backlund, of the Observatory of Pulkowa, was able to make some good observations at Novaya Zemlya.—On the transformations of the equations in dynamics, by M. Paul Painlevé.—On a proposition in mechanics, by M. F. Siacci.—On a doubly recurring series of points always homocyclic, by M. P. Serret.—On the electric convection following the lines of force produced by the Röntgen rays, by M. Aug. Righi. Experiments are described which tend to show the existence of a convection following the lines of force.—The utility in radiography of a screen coated with phosphorescent sulphide of zinc, by M. C. Henry. The zinc sulphide screen, wrapped in carbon paper, is covered with the object to be examined and exposed to the radiation of a Crookes' tube for some minutes. On removal to a darkened room the image shines for at least a quarter of an hour, so that the smallest details of the image can be made out. The light emitted by glow-worms was found to be capable of penetrating blackened paper, and affecting a sensitive plate underneath.—The quaternary beds of the Micoque, by MM. G. Chauvet and E. Rivière.—Note on magnesium sulphide, by M. N. Bignan.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—British Association, Liverpool, 1896: Handbook to Liverpool, &c. (Philip).—An Archæological Survey of the United Kingdom: Dr. D. Murray (Glasgow, MacLehose).—On the Adjustment and Testing of Telescopic Objectives, 2nd edition (York, T. Cooke).—The Principles of the Transformer: Dr. F. Bedell (Macmillan).—"Made in Germany": E. E. Williams, 3rd edition (Heinemann).—Entomological Notes for the Young Collector: W. A. Morley (E. Stock).—British Butterflies: J. W. Tutt (Gill).—Elements of Astronomy: Sir R. S. Ball, new edition (Longmans).

Pamphlets.—Les Applications de L'Electrolyse a la Métallurgie: M. U. Le Verrier (Paris, Gauthier-Villars).—Vierter Jahres-Bericht des Sonnblick-Vereines, 1895 (Wien).—Arithmetic for Promotion, Scheme B: Lock and Macdonald, Part 5 (Macmillan).

CONTENTS.

THURSDAY, SEPTEMBER 10, 1896.

RECENT ORNITHOLOGY.

A Vertebrate Fauna of the Moray Basin. By J. A. Harvie-Brown, F.R.S.E., and T. E. Buckley, B.A., F.Z.S. 2 vols. Pp. xx + 262 and 309. (Edinburgh: David Douglas, 1895.)

British Birds' Nests: How, where, and when to find and identify them. By R. Kearton, author of "Birds' Nests, Eggs, and Egg Collecting." Introduction by R. Bowdler Sharpe, LL.D. Illustrated from Photographs, by C. Kearton, of Nests, Eggs, Young, &c., in their Natural Situations and Surroundings. Pp. xx + 368. (London, Paris, and Melbourne: Cassell and Co., Ltd., 1895.)

British Sea Birds. By Charles Dixon. With eight illustrations by Charles Whymper. Pp. ix + 295. (London: Bliss, Sands, and Foster, 1896.)

A Hand-book to the Birds of Great Britain. By R. Bowdler Sharpe, LL.D., Assistant Keeper, Zoological Department, British Museum. Vol. iii. Allen's Naturalist's Library. Pp. xii + 338. (London: W. H. Allen and Co., Ltd., 1896.)

"THE Vertebrate Fauna of the Moray Basin," by Messrs. Harvie-Brown and Buckley, is the latest addition to the series being issued by them on the Vertebrate fauna of Scotland. They have already given us the Vertebrate fauna of Sutherland, Caithness, and West Cromarty; of the Outer Hebrides; of the Orkney Islands; and of Argyll and the Inner Hebrides. When we get, as we are promised before long, that of West Ross and Skye, and of Shetland and Dee, the northern parts of Scotland, so far as the section of its fauna with which our authors concern themselves, will be complete.

The area dealt with in the present volume is extensive, embracing "all the country drained by the rivers flowing into the Moray Firth . . . including the greater part of Sutherland, Ross, Inverness . . . Banff, Moray and Nairn." "We have endeavoured," say the authors, "from within our own narrow horizons in this, as in previous volumes of the series, to indicate the importance of natural areas and boundaries as determining to a large extent the faunal values." The greater part of the first volume, therefore, describes the water system, topography and physical features of the Moray Basin—"whose landward portion [is] hemmed in by some of the highest mountains of Scotland, and its seaward area similarly enclosed by the funnel-shaped contours of the shores"—and discusses the relation of these to the resident and migrant species inhabiting it. Forty-two species of mammals, 255 of birds, and nine of reptilia and amphibia are enumerated from the Moray Basin, with lengthy and valuable notes on their distribution, dates of breeding, and habits. No account is given of the marine or fresh-water fishes, beyond incidental mention, but we have an important chapter by Dr. R. H. Traquair, F.R.S., on the extinct vertebrates found in the different geological formations in the region, illustrated by several plates of restorations of the fishes for which the rocks of the Moray Basin are remarkable.

Such small defects as a style somewhat discursive, and sentences often rather involved and occasionally less pellucid than could be desired, will be readily forgiven the two naturalists who have laid their brethren under great obligations by this addition, which can hardly be too highly praised, to their valuable series of local faunas of Scotland. In addition to the palæontological plates, and several of nests and nesting-places of birds, excellently reproduced by process, these volumes are embellished by a number of exquisite photogravures (by Annan, of Glasgow) of scenery in the Moray region interesting to the naturalist. No book deserves to be commended—even if good otherwise—which fails to provide a full index and, where topography is dealt with, a good map. Both are to be found in "The Moray Basin." The map, which includes Scotland north of latitude 56½°, by Bartholomew, whose cartographical fame is world-wide, is beautifully clear yet full of detail. For all that is excellent in the publisher's art and craft, the name of David Douglas, by whom these volumes are given out, is sufficient guarantee; and they are worthy companions to their predecessors in the well-known sport and natural history series, issued from Castle Street, Edinburgh.

The book second on our list, by the brothers Kearton, owes its existence to a series of photographs of British birds' nests and eggs taken "in their natural situations and surroundings." They claim theirs as "the first practical attempt to illustrate a manual on the subject from photographs taken *in situ*," and characterise their pictures as "unique." Surely we have before the appearance of this volume had bird-articles illustrated by process blocks of birds' nests and eggs in their natural situations; and has not Mr. Welch, of Belfast, published a charming series of photographs of birds' nests taken also *in situ?* The manual before us, whose letter-press is from the pen of Mr. R. Kearton, presents us with the species-breeding in this country arranged in alphabetical order, and gives a short description of the parent birds (whose scientific names are, we regret to see, omitted), of the locality, situations and materials of the nest, and of the colour and size of the eggs and their time of laying—all sufficiently accurate, and of much value where the authors speak from personal observation. The illustrations, of which there are over a hundred, most of them well printed, are from photographs by Mr. C. Kearton. They by no means illustrate the nests of all the birds described in the text; but, on the other hand, those of many species are given which few even of those who are bird-lovers are likely ever to see unless they make a special journey for that purpose. Mr. C. Kearton has spent an enormous amount of time, energy and perseverance, and overcome troubles and disappointments of no ordinary kind, and he has bravely—occasionally foolhardily—hazarded his life, poised on the slender tops of high trees, or dangling from the face of precipices, in obtaining illustrations for his book. We agree with Dr. Sharpe, who, in the commendatory preface by which he introduces our authors to the public, remarks that the way in which they have overcome the very serious difficulties presented by their task "proves that in addition to the native British pluck, the

U

true love of natural history is necessary to accomplish such a result as they have achieved." Much as we admire the one, and feel in fellowship with the other, we cannot help saying that the results are ornithologically unsatisfactory, and expressing what we have long realised, that photographs direct from nature are not the best means of representing birds' nests and eggs. So little of the surroundings can, as a rule, be got into a half-plate, that it is difficult, if the nest and eggs are to be visible at all, to form any true idea of the situation or of the materials of the nest; nor, except under very favourable circumstances, can a standard of size be introduced to correct, as is so often needed, the retinal impression. Unless also the photograph be taken perpendicularly above the nest, which is unsatisfactory, the eggs cannot be seen in the nest unless they are elevated or, what is equally to be deprecated, the nest be tilted, as in the song-thrush's on page 299. If, again, we compare the nests of the gadwall and the pheasant, the character, form and uniform surface of the eggs are so similar, that both nest and eggs might belong to either bird; and a "Skylark's nest on the crown of a furrow," conveys the impression of being situated on the face of a rocky wall. There seems to be greater scope for the "photographic naturalist" in dealing with nestlings. The young "Grey-lag geese" and the "Golden eagle's eyrie, with young," are both delightful.

Notwithstanding these defects in some of the illustrations, inseparable from the process employed, or due to the awkward places whence the views were photographed, this volume, which is attractively produced, will doubtless have a wide circulation among young British ornithologists.

Mr. Charles Dixon, who appears under the auspices of a different publisher than heretofore, claims audience with a new book, "British Sea Birds," in which we are pleased to find fact more plentiful than fancy. It has been our far from pleasant duty oftener than once to criticise adversely the theories and speculations he has advanced. On the present occasion, however, we feel considerable gratification in being able to recommend his chatty articles on the birds to be found along our coasts. There is nothing new or striking in the volume; but it will prove an agreeable and instructive companion to many of those who, during their sea-side holidays, take an interest in the birds they meet with, and desire to know something about them. Besides describing our strictly marine birds, Mr. Dixon contributes a chapter on land birds that are constantly to be found frequenting the shore or the cliffs. The volume is very prettily got-up and illustrated by eight excellent full-page plates by C. Whymper.

The third and penultimate volume of Dr. Sharpe's "Handbook to the Birds of Great Britain," in Allen's Naturalist's Library, concludes his account of the ducks (*Anatidæ*), and describes the herons, storks and ibises (*Ardeiformes*), the cranes (*Gruiformes*), and the bustards and plovers (*Charadriiformes*), in all ninety-two species. The present volume maintains the high standard of excellence of its predecessors; but the illustrations, though perhaps as good as can be expected for the exceedingly low price at which each volume is published, are not above criticism.

BRITISH MOSSES.

The Student's Handbook of British Mosses. By H. N. Dixon, M.A., F.L.S.; with Illustrations and Keys to the Species by H. G. Jameson, M.A., Author of the "Illustrated Guide to British Mosses." Pp. xlvi + 520; 60 plates. (Eastbourne: Sumfield, 1896.)

THIS book appears to us a very useful one. The author observes that Wilson and Berkeley are out of date, that Hobkirk's synopsis is too compressed to be of great service to the less practised collector, and that Braithwaite's great work is expensive and at present incomplete. There is, therefore, room for a new work on the subject, and the present volume appears to be a very praiseworthy attempt to fill the vacant space.

The work consists of a brief introduction; a glossary; a key to the genera; a description of the orders, genera, and species; an index, including synonyms; and 60 pages of plates. The key to the genera is intended to help a student to discover the genus of his specimen, and is based on practical considerations and not on system. The student should, perhaps, be warned not to suppose that there is more than an accidental connection between the genera which get thrown together by this process. The first group to which the student is referred is headed "A. Leaves distichous, inserted in two rows on the stem," and under this we find the genera Schistostega belonging to the order Schistostegaceæ, Swartzia belonging to the Dicranaceæ, and Fissidens belonging to the Fissidentaceæ. For the purpose of aiding the student in his hunt, this method of dealing with prominent features of the plant is very convenient. In the body of the book the name of the genus under consideration is printed at the top of the right-hand page, and in the text the genera are numbered throughout; if the number were also printed at the top of the page—thus, "12 Swartzia," or "xii. Swartzia"—it would make the process of turning to the genera from the key to the genera much easier and quicker.

Another suggestion which we venture to make to the authors for the second edition relates to the index. If one wants to see the plate illustrating, for instance, *Hypnum aduncun*, one must either look through the plates till it is found, or one must go to the index; from that to p. 458 of the treatise, from which there is a reference to Tab. lvi. O. If the index gave the following entry, "*Hypnum aduncun*, Hedw., 458, lvi. O," the reader would be saved this trouble, and the index would serve both for plates and text.

In dealing with the genera, our author gives us not only a description of the genus, but a table dichotomously arranged as a guide to the several species; and in his descriptions, both of genera and species, he has adopted the very useful practice of printing in italics the salient and most distinctive characters.

Mr. Jameson, whose useful illustrated guide to British mosses we reviewed in March 1894, has aided Mr. Dixon in the preparation of this work. He has re-written the keys to the genera and to the species, and the plates to the present work are based on those of Mr. Jameson, but have been re-drawn, and in many cases improved and added to.

We have not, of course, made use of this new volume practically; but from what we see of it, we should, without hesitation, recommend it to any person beginning the delightful study of mosses as the most likely of all those within our knowledge to suit his needs. E. F.

OUR BOOK SHELF.

Catalogue of the Described Diptera from South Asia. By F. M. Van der Wulp. 8vo. Pp. 220. Published by the Dutch Entomological Society. (The Hague: M. Nijhoff, 1896.)

COMPARATIVELY few entomologists interest themselves in *Diptera*, and therefore the number of species of the order enumerated in the present catalogue is only 2889, and doubtless represents only a small percentage of those actually existing in the rich fauna which it samples; for the *Diptera* are probably the third most numerous order of insects, surpassed only, according to the indications of our present knowledge, by the *Hymenoptera* and *Coleoptera* in the total number of species which they may be expected to include. Prof. Van der Wulp is recognised as one of our first living authorities on *Diptera*, and his work will prove of great use to specialists, especially as M. Bigot's "Catalogue of the *Diptera* of the Oriental Region," published in the *Journal* of the Asiatic Society of Bengal for 1891 and 1892, is both imperfect and inaccurate. The introductory part of the work is written in English, and includes a "Review of the Literature of Oriental Dipterology" and a bibliographical list of books and papers consulted. There is also a table of contents at the beginning, and an index of families and genera at the end. We cannot have too many books of this description; for although the number of undescribed species of insects is enormous, it is perhaps even more important to attempt to keep pace with the rapidly-accumulating mass of descriptive matter by means of carefully compiled monographs and synonymic reference catalogues, than to confine our energies to piling up additional descriptions by the hundred or the thousand.

W. F. K.

History of Modern Mathematics. By David E. Smith. (London: Chapman and Hall, Ltd., 1896.)

"HIGHER Mathematics," edited by Mansfield Merriman and Robert S. Woodward, is a text-book for classical and engineering colleges, and is a work containing 600 pages. Each chapter is written by a different author, and is devoted to some special branch of mathematics; chapters i., ii., iii., &c., dealing with solutions of equations, determinants, and projective geometry respectively. The eleventh and last chapter, a reprint of which we have before us, is written by Mr. David E. Smith, of the Michigan State Normal School, and deals with the "history of modern mathematics." Of course it has not been intended here to give a complete history of modern work, but just a sufficient survey of the whole domain to give a student an intelligent idea of the way in which the more recent advances have been made, and the ends gained thereby. Each mathematician has, as a rule, his own speciality; but each of these is one link in the chain which, when put together, forms the whole. Such a history as Mr. Smith gives here fulfils this point, and its shortness and conciseness will be favourable to students of mathematics. The text is increased in value by the numerous footnotes, and a short bibliography is given at the end; this latter is, however, by no means complete, as the author remarks, but he gives references for those who wish to go further afield. For a biographical table of mathematicians he refers to Fink's "Geschichte der Mathematik," p. 240, and for the names and positions of living mathematicians to the "Jahrbuch der Gelehrten Welt," published at Strassburg.

Graphical Calculus. By Arthur H. Barker. (London: Longmans, Green, and Co., 1896.)

A VERY timely book; and useful to instructors in the elements of the subject in providing a number of apt and eloquent illustrations of fundamental ideas. It represents a series of lectures addressed to engineering students, liable to be repelled by pure abstractions, and preferring concrete representations in which their ideas can take root; a complete contrast to the ordinary mathematical text-book of the school of Todhunter. The author should point out that the gradient of 1 in 100 (p. 13) means an angle whose tangent is 0·01 only in the indoor mode of reckoning on a plane; but that in construction of the railway, the angle is made with a sine of 0·01; the two modes of measurement are indistinguishable practically.

Integration is introduced simultaneously with differentiation, as in many respects a simpler idea to grasp; we can realise the growth of a tree at the end of a year, although the rate of growth is imperceptible. Our ordinary mathematical text-books make the mistake of keeping integration in the background too long. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I MUST confess to still feeling some difficulty in understanding my friend Prof. Lankester's position, notwithstanding his explanations.

The correlation principle was arrived at by Mr. Darwin after a careful examination of a large body of facts. I quote the carefully considered words in which he sums up his conclusions:—

"Correlation is an important subject; for with species, and in a lesser degree with domestic races, we continually find that certain parts have been greatly modified to serve some useful purpose; but we almost invariably find that other parts have likewise been more or less modified, without our being able to discover any advantage in the change. No doubt great caution is necessary in coming to this conclusion, for it is difficult to overrate our ignorance on the use of various parts of the organisation; but, from what we have now seen, we may believe that many modifications are of no direct service, having arisen in correlation with other and useful changes." ("Animals and Plants under Domestication," vol. ii. pp. 354–5.)

It does not appear to me that there is anything in this which conflicts with the doctrine of the "utility of specific characters." The non-useful parts of the correlated chain (if any) are sustained by the useful, and the *whole* seems to me part of the "specific character." If Prof. Lankester had no other object but to call attention to Mr. Darwin's correlation principle, I think this was a little superfluous, for it is part of the mere grammar of Darwinism.

But the point of his speech at the Linnean Society, and of the subsequent account he gave of it in NATURE, appeared to me to go a good deal beyond this, and to be of considerable interest and importance.

In the cases cited by Mr. Darwin, the correlated structures are almost all, to use Prof. Lankester's words, "obvious and measurable." This we would expect in the correlated variation of homologous parts on which Mr. Darwin lays such stress, and which form the bulk of the instances which he gives.

Prof. Lankester's "suggestion" was that "obvious species marks may be only superficial and non-significant phenomena correlated . . . with other less obvious but really important life-saving peculiarities, which might well escape the observation of the describer of specific characters." He then adduces Wells's theory as "a case which seemed to [him] most striking and suggestive in connection with the utility of specific characters." And so I think it is. I ventured to express an opinion that if established it would prove very damaging to, at any rate, the universatility of that doctrine. I certainly supposed that that was Prof. Lankester's object in bringing it forward.

He now adds that he might as well "have used any of the other cases collected by Mr. Darwin." It is not a very material point, but I do not find that Mr. Darwin makes any reference to Wells's theory in his discussion of correlation, nor do I see any in the body of the sixth edition of the "Origin of Species," though a passage is quoted from Wells's paper at p. xi. of the "Historical Sketch" which is prefixed to it. It had, however, independently occurred to Mr. Darwin, and he discusses it in a somewhat different connection in the "Descent of Man" (i. pp. 242–245). He remarks:—"That the immunity of the negro is in any degree correlated with the colour of his skin is a mere conjecture; it may be correlated with some difference in his blood, nervous system, or other tissues." And he concludes:—"I endeavoured with but little success to ascertain how far it held good." Elsewhere he gives cases to show that "differences in colour are correlated with constitutional differences." But these, though interesting, seem to me too obscure to found any definite conclusion upon. And no attempt is made to show on what material basis, subject to variation, the constitutional difference depends.

The correlation principle as originally defined dealt then with obvious and measurable characters. It is extended by Prof. Lankester's "suggestion" to what is obscure, may be unknown, and perhaps unknowable. In considering the probable utility of any specific character we shall, if the extended principle be accepted, be always open to the objection that we cannot show that the character is not the outward and visible sign of some unobservable internal peculiarity. But that is a position which I do not think we are bound to accept till something more than a hypothetical case has been established.

To sum up: Mr. Darwin based the correlation principle on what is concrete and tangible; Prof. Lankester extends it to what is intangible and hypothetical. It is not a question of what is "apostolic and orthodox," but of what is susceptible of reasonable proof.

As I do not propose to continue this discussion any further, I will take the opportunity of saying that I think it is a matter for regret that, as Prof. Lankester was present at the meeting of the Royal Society when Prof. Weldon's paper was read, he did not deliver himself on that occasion of his somewhat belated criticism. Prof. Weldon's work is of extraordinary interest, and one cannot but admire the self-sacrifice with which such laborious investigations have been prosecuted. If they want a defence, I think the following passage from the "Origin of Species" supplies it.

"It may metaphorically be said that natural selection is daily and hourly scrutinising, throughout the world, the slightest variations; rejecting those that are bad, preserving and adding up all that are good; silently and insensibly working, *whenever and wherever opportunity offers*, at the improvement of each organic being in relation to its organic and inorganic conditions of life. We see nothing of these slow changes in progress, until the hand of time has marked the lapse of ages, and then so imperfect is our view into long-past geological ages, that we see only that the forms of life are now different from what they formerly were." (Sixth edition, pp. 65–66.)

I do not myself see how the slow and ordinarily imperceptible, but inevitable action of natural selection can be demonstrated except by the statistical method. But, firmly as I believe in the inevitableness of that action, I confess that the results attained by Prof. Weldon surpassed my expectations. I am unable to agree with Prof. Lankester, that the investigation does not satisfy the canons of scientific inquiry. The hypothesis on which it appears to me to be based is, that the mean configuration of any organism at any moment is an optimum. In order to test that by the statistical method, the choice of measurements is a mere matter of convenience.

W. T. THISELTON-DYER.

Kew, August 29.

Thermometer Readings during the Eclipse.

I STARTED on July 30 in the *King Harold*, and arrived at Vadsö on August 6. On board this vessel, amongst others, were Prof. Rambaut and Dr. Hugh R. Mill, of the Geographical Society, who I see has sent a note which appears in NATURE of August 27, as to some observations of temperature he took during the eclipse. I was constantly with Prof. Rambaut on the island at Vadsö, and he particularly requested me to observe the temperatures of sun, and shade thermometers during the eclipse at the position he had taken for his observations, which were specially directed to the degree of polarisation of different parts of the corona. I enclose a diagram of my observations, which Prof. Rambaut has suggested I should send to NATURE, should you think they are worth recording. The fall of the sun thermometer (which unfortunately was fully shaded by cloud) was, from 4h. 10m. to just after totality, 2°, and its recovery

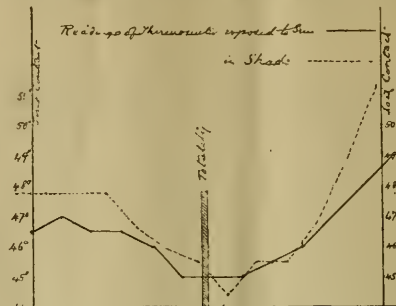

Diagram of observations of sun, and shade thermometers during the eclipse of the sun, August 9, taken at Vadsö.

from that point to 5h. 56m., last contact, was 3°·6. The shade thermometer showed greater variations, viz. a fall of 3°·35, and subsequent rise at 5h. 50m. of 5°·6.

H. WOLLASTON BLAKE.

8 Devonshire Place, W., September 3.

Sailing Flight.

MR. PEAL (NATURE, vol. liv. p. 317) having again brought up this matter for discussion in the columns of NATURE, I would like to make a new suggestion concerning it, which I have long had on my mind. It will be remembered that Lord Rayleigh (NATURE, vol. xxvii. p. 534) assumed an increase of wind-velocity with altitude to explain the facts of circular soaring, and that quite recently Langley (*Amer. Journ. Sci.*, vol. xlvii. p. 41) has tried to explain the same phenomenon by the assumption—supported in his case by direct observation—that the velocity and direction of the wind is subject to great and rapid changes. Concerning this latter statement, I must say that although in a thunderstorm great irregularities can be observed in the upper air-currents, the shape and relative constancy of small clouds in fine weather seem to show that under ordinary conditions the upper air-currents are much steadier than Langley assumes, and that, therefore, soaring birds can by no means always depend on the presence of wind-irregularities sufficiently great to sustain them. Although no doubt wind-velocities generally increase with altitude, I do not believe that such an increase will *always* be present, nor that it will, when present, be usually sufficiently great to produce the force necessary for raising a bird. We observe, however, that birds do soar nearly always, perhaps even more frequently in fine weather, when the currents are more steady, than in rough weather, when they are more irregular.

Under these circumstances it seems to me that neither Lord Rayleigh's nor Langley's assumptions concerning the source from whence these birds derive the power of overcoming gravity can be correct. It seems to me, doubtless, that a steady horizontal wind of equal velocity in different altitudes *does* enable them to soar and to rise. It is remarkable that this soaring without loss of elevation is always accompanied by *circling*. Elevation is not known to occur without circling, as it might if Langley's views were correct. Were the bird attached to the earth by a string like a kite, it could be and, if the wing-planes were placed in proper positions, would be sustained and raised by a purely horizontal and steady wind. Now it seems to me that the *circling replaces the string*. A circling top retains its position on account of the force in its rapidly circling parts. Could not the soaring bird produce—through circling—a similar stability which, acting like a kite-string, would enable it to oppose itself to the wind, and thus convert the horizontal wind-force partly into a vertical, lifting force? Mr. Peal, in his last letter (*l.c.*) very correctly remarks that the connecting-

line of the wing-tips does not lie horizontally, but obliquely, so as to describe in moving, a cone, apex downward. This slant gives, through the resistance of the air, a certain degree of rigidity to the system represented by the soaring and circling bird, which corresponds to the rigidity that holds the parts of the top together, and prevents them from flying off in tangents.

Being myself a zoologist, and not a mathematician, I cannot venture to state this hypothesis otherwise than in the shape of a question; perhaps one of the mathematical readers of NATURE will kindly take the trouble to answer it.

Czernowitz, August 23. R. VON LENDENFELD.

THE CONWAY EXPEDITION TO SPITZBERGEN.

THE expedition organised by Sir Martin Conway for the exploration of the interior of Spitzbergen left London on June 2, and first sighted the island on June 17, the exact tercentenary of its discovery by Barentz. The northern ice sheet having broken up exceptionally early this year, the floes off the western coast of Spitzbergen were unusually heavy, and somewhat delayed the arrival in Advent Bay. The expedition landed the stores there on June 20. In accordance with the plan of operations arranged, the members divided into two parties: one party, consisting of Sir Martin Conway, Mr. E. J. Garwood, a well-known geologist and Alpine photographer, and the writer, proceeded to cross Spitzbergen to the east coast. The other party, composed of Mr. Trevor Battye, the ornithologist with the expedition, and Mr. H. E. Conway, the artist, cruised about Ice Fjord and its two chief bays, in order to collect birds and make sketches.

Till the present year very little was known of the interior of the country. The coasts have been carefully surveyed by many expeditions, of which those of Parry and of various Swedish explorers, notably the series organised by Baron Nordenskiöld, are of the first importance. But hitherto the only contributions to our knowledge of the interior were those of the late Gustav Nordenskiöld and M. Rabot. The former marched for three days across the ice-sheet from Hornsund to Bel Sound, along a line parallel to the west coast and some miles inland. M. Rabot made a three days' excursion up a valley going inland from the head of Sarsen Bay. With these exceptions, exploration had been limited to the coast, and to within a day's march of it. Sir Martin Conway therefore took out two ponies and sledges, with which to provision some inland camps. The ponies answered well, but the sledges broke down repeatedly, and thus greatly delayed progress.

The principal geographical work of the expedition was the first crossing of Spitzbergen, from Advent Bay to Agardh Bay. The country traversed was mapped by Sir Martin Conway, while his two companions worked out the geology of the country and made collections of its flora and of its very limited fauna. Subsequently the whole expedition sailed northward to the Seven Islands, and through Kinlopen Strait and across Olga Strait to near King Charles' Islands. An effort to complete the circumnavigation of Spitzbergen was nearly successful, but failed owing to the passages into Sta Fjord being blocked by fast ice. Mr. Garwood and Mr. Battye ascended Hornsund Sind, the highest peak in Spitzbergen.

In regard to the biological results, it is too early to estimate their value, for novelties can only be expected among the invertebrates, which have not yet been examined. The only land mammals are the bear, arctic fox, and reindeer, of which the last are abundant. Birds are individually numerous, but the species are few; of the twenty-five authentically recorded species, we saw all but the snowy owl (*Nyctea nivea*). One addition to the list might have been made, had we been able to carry a gun across the island; for we saw an unrecorded species on the shore of Agardh Bay. Several dredge hauls were made in Advent Bay and Hornsund, yielding various species of worms, mollusca, crustacea, ophuiroids, &c.

Botanical collections were made during the traverse of the island in order to contrast the flora of the inland valley, of the high plateaus, and of the nunataks, with that of the coast. The flora is remarkably uniform, and the influence of height has less effect than those of situation and season. The species found on the mountain summits in the middle of the summer were the same as those found on the coast at the beginning of the spring. As the season advanced the species first found in flower on the lowlands and in sheltered valleys were succeeded by another set; but at any time it was only necessary to seek exposed and barren positions, or to climb above the snow line, to find the first flora still in flower.

Spitzbergen offered better opportunities for geological than for either zoological or botanical work. The rock sequence includes representatives of the Archæan, Lower Palæozoic, Devonian, Carboniferous, Trias, Jurassic, and Middle Tertiary. The coast series has been described by many workers, including Keilhau, Torell, Loven, Lamont, Nordenskiöld, Nathorst, de Geer, and others; but as the interior had not been visited, we had there a fresh field of work. In this I had the good fortune of the co-operation of Mr. E. J. Garwood; together we mapped the belt of country between Advent Bay and Stor Fjord, and made collections from each of all the geological systems that occur in Spitzbergen. Our work was greatly facilitated by the simplicity of the geology of the country; the sections are numerous and clear, and the structure is often shown with diagrammatic clearness.

Our best opportunity for the study of the Archæan rocks was given by the bare cliff sections at Walden Island, one of the Seven Islands situated in lat. 80° 38′. Here we found that this series was formed of a group of schists which have been invaded by two sets of intrusive gneisses; great blocks and seams of the schists are included in the gneisses, while veins from the latter cut upward into the schists.

The general stratigraphical sequence has many points of interest. Great stress is often laid on the absence from Spitzbergen of any indication of glacial action in times earlier than the Pleistocene; and also on the fact that the occurrence of fossil coral reefs, and beds containing warm, temperate, or even sub-tropical plants, shows that the climate before the Pleistocene epoch was quite different from that of the present time. Our evidence, however, greatly simplifies the task of explaining these difficulties; that remarkable changes of climate have happened, is unquestionable. One such is probably in progress still. But these changes of climate are reduced to much narrower limits than seems to be generally considered. We found signs of glacial action in the deposits of, at least, two different eras before those of the "great ice age." Moreover, the so-called coral reefs are not coral reefs, and might have been formed in the adjoining seas; and the fossil plants do not indicate so mild a climate as those of the Miocene beds of Southern Greenland. In fact, the whole of the fossil faunas and floras from the Devonian onward are comparatively poor in species, and appear to have lived under unfavourable conditions, and their existence in Spitzbergen may all be explained by the assumption of only a sub-arctic climate.

One of the main temptations Spitzbergen offers to the geologist is a magnificent opportunity for the study of glacial action; for we may see there marine and land ice working side by side. As our time on the coast was short, we naturally saw most of the inland glaciers. These are very different from those of Switzerland; for example, they have practically no *névé* fields. All the snow that falls on the collecting-ground at the head of the glacier turns to ice *in situ*. Time after time we ascended glaciers, expecting to be soon stopped by

reaching snow-covered crevassed ice; but, to our surprise, we found that the apparent *névé* field was a slope of ice reaching to the col, or the mountain summit. We naturally devoted much attention to a comparison of the deposits accumulated by marine and land ice. Both lay down glacial beds of very varied characters. We had no difficulty in finding cases of the formation of typical boulder clay by land ice. We also kept in mind the questions of the possibility of the uplift of material through ice, and of the existence of a differential flow in glaciers. To take one case of the former: in the moraine lying on the eastern face of the "Ivory Gate Glacier" we found many fragments of shells which had been lifted above the level of the old sea beaches, whence they had been derived. This supplied us with one clear case of the uplift of material, and the sections round the snout of this glacier left no doubt as to the method by which this is effected. The proof of a differential flow in glaciers is even more conclusive; the evidence of the extent and importance of such movements strikes us as the most impressive fact in the glacial geology of Spitzbergen. Many of the glaciers terminate with precipitous faces; these show that the layers of ice have the false-bedded arrangement that is familiar from photographs of the Greenland glaciers. Study of the sections shows that beds of englacial drift are being uplifted or carried in a direction different from that of the main movement of the ice. As we climbed and sketched the face of the "Booming Glacier" at the head of Advent Vale, we could not but recall Mr. Goodchild's paper on the "Glacial Phenomena of the Eden Valley" (1872); for we could see deposits of the same characters as those he there describes being formed by ice, acting in the way which he there assumes it must have acted.

The raising of beach material is also effected by the stranding of bergs and floes upon the sea shore; but the range of this action is not very great. The Spitzbergen walrus and seal hunters and fishermen agree that ice is never forced on shore more than one hundred yards inland, or to a height of over fifty feet.

Marine glacial deposits occur in many parts of Spitzbergen; but moraines formed in the sea differ from those formed on land—by their shape, by the character of the material, and its arrangement.

It is, perhaps, unnecessary to add that the glaciation of Spitzbergen was solely due to a local glaciation. We found no evidence of any great polar ice cap. Had any such have existed and overridden Spitzbergen from the north, we ought to have seen its traces. On the contrary, along the north coast the ice movement was from south to north.

J. W. GREGORY.

THE LAST DAY AND YEAR OF THE CENTURY: REMARKS ON TIME-RECKONING.

THE late Astronomer Royal, Sir George Airy, once received a letter requesting him to settle a dispute, which had arisen in some local debating society, as to which would be the first day of the next century. His reply was: "A very little consideration will suffice to show that the first day of the twentieth century will be January 1, 1901." Simple as the matter seems, the fact that it is occasionally brought into question, shows that there is some little difficulty connected with it. Probably, however, this is in a great measure due to the circumstance that the actual figures indicating the century are changed on January 1, 1900, the day preceding being December 31, 1899. A century is a very definite word for an interval, respecting which there is no possible room for mistake or difference of opinion. But the date of its ending depends upon that of its beginning. Our double system of backward and forward reckoning leads to a good deal of inconvenience. Only the other day I was reading in a high-class scientific periodical (the *Journal* of the Astronomical Society of Wales), that the Athenian expedition under Phocion to succour Byzantium (attacked by Philip of Macedon) took place in B.C. 339, and that that was now exactly 2235 years ago.[1] But it is evident that as there was no year 0, and B.C. 1 immediately preceded A.D. 1, the interval from any date in a B.C. year to the same in an A.D. year is found not by simply adding the respective years, but by afterwards subtracting 1 from this sum. Our reckoning supposes (what we know now was not the case, but as an era the date does equally well) that Christ was born at the end of B.C. 1. At the end of A.D. 1, therefore, one year had elapsed from that event, at the end of A.D. 100, one century, and at the end of 1900, nineteen centuries.

Believing that our Lord was born in the autumn or towards the end of B.C. 5, I once stated that our ordinary reckoning was five, not four, years in error, because the interval from a given date in B.C. 5 to the same in A.D. 1 is five years. But I was properly pulled up for saying so, because our reckoning supposes that Christ was born in B.C. 1, and B.C. 5 is the fourth year before that, so that if we could now revert to the correct year of the Nativity, the present year would be 1900, *i.e. the nineteen hundredth year after the birth of Christ.* At its close nineteen centuries from that event would be completed, and the twentieth century commence with January 1 next year, which would be called 1901. Here is where the apparent difficulty comes in. Some people fancy that the year 1900 means 1900 years after the birth of Christ; but the years are in fact ordinal, not cardinal, numbers, and the century is completed, not at the beginning, but at the end of that year. The mistake is of the same kind as if we should conclude from a man being, for instance, in his sixty-second year that he was sixty-two years old. A recent writer in the *Times* points out that though the same argument applies to the hours of the day, we do in fact use cardinal numbers in this respect; and when we say, for instance, 4 o'clock in the afternoon, we mean that four whole hours have passed since noon, whereas by analogy with the number indicating the year, we might mean the fourth hour. This of course is what the Germans do, in speaking of time between two consecutive hours, *halb vier*, for instance, with them meaning half-past 3, or the fourth hour, half gone. But it would be impossible to designate by half-*past* 4, for instance, half an hour or thirty minutes in the fifth hour or of hour five; and the French idiom equally necessitates counting the portions of an hour from the hour as a cardinal number.

It is clear then that the year, as we call it, is an ordinal number, and that 1900 years from the birth of Christ (reckoning it as we do from the end of B.C. 1) will not be completed until the end of December 31 in that year, the twentieth century beginning with January 1, 1901, that is (to be exact), at the previous midnight, when the day commences by civil reckoning. The writer referred to above, truly says that in speaking of months of the year and days of the week we also use ordinal numbers; but in these, when that method of designating them is used, we actually say so, and call them the first or second, &c., month or day. The year, on the other hand, is always spoken of as a cardinal number; but probably this is on account of its number being large. Had the reckoning from the true or supposed date of the birth of Christ been commenced in the first century, the years would doubtless have been called, like those of the reign of a king or queen, the first, second, &c., or fiftieth, sixtieth, year. In mentioning the hours of a day, the matter becomes somewhat different, because we see them

[1] The expedition really took place late in the summer of B.C. 340, and there may be a misprint here. The article is in reference to a medal struck at Byzantium, representing an occultation which occurred at the time, and is the origin of the present Turkish standard.

marked and hear them struck on a clock. We think therefore of an hour not as an interval of time, but as an instant, which is that of the completion of the hour, 4 o'clock or 4 by the clock, meaning that four complete hours have passed since the beginning of the clock-round. When this is noon, and the hours afternoon hours, all is logical enough. We are obliged to call the beginning of the round the completion of the preceding; because though a clock may mark 0, as clocks used in observatories do, we cannot indicate nothing by a strike. Our ordinary habit, however, becomes illogical when we speak of morning hours and call them a.m. or ante-meridiem; for eight hours, for instance, before noon should mean what we call 4 o'clock in the morning or 4 a.m. To be logical, the morning or a.m. hours should diminish instead of increasing; but the usage cannot well be altered, and it is not likely that ordinary people will ever adopt the astronomer's plan and count the whole day through twenty-four hours, even if astronomers try to conciliate them by dropping their practice of beginning the day at noon. For this there is now much less reason than there was in early days of the science, when it was thought desirable to keep a whole night's observations under one date; for modern astronomers make a considerable number of observations in daylight and during the day hours.

W. T. Lynn.

POPULAR GEOLOGY.[1]

Some fifteen years ago, if a book had been published under the title of "The Scenery of Switzerland," the reading public might have expected glowing descriptions of the magnificent mountains, the wild waterfalls, the quaint châlets, the dangerous passes and precipices of that wonderful Alpine rampart of Switzerland

> "Which serves it in the office of a wall,
> Or as a moat defensive to a house,
> Against the envy of less happier lands."

And it would have been somewhat startled on opening the book to find the first chapter dealing with the "Geology of Switzerland," and bristling with a supply of technical terms seldom to be found outside a geological text-book. Nevertheless, that is how Sir John Lubbock's new book opens, and the title is accordingly somewhat qualified on the inner fly-leaf, where it reads in full, "The Scenery of Switzerland and the Causes to which it is due."

We have already had the æsthetic aspect of the Alps presented to us by such writers as Symonds, Ruskin, and Leslie Stephen; the mountaineering aspect by such famous climbers as Whymper, Freshfield, and Conway; the scientific aspect by Forbes, Tyndall, Bonney and others; and now Sir John Lubbock seeks to combine the æsthetic and the scientific aspects. It may be said at once that the book supplies to the cultured tourist a want which has been felt more and more for some years. Years during which Dr. Lunn's inexpensive tours have brought a journey to Switzerland within the reach of modest incomes, and when popular lectures on physical and geological subjects have attracted ever-increasing interest. Besides, these are *fin de siècle* days, when the mere sensuous enjoyment of the beauties of Swiss mountains is not enough to gratify the tourist! He wants to surmount their difficulties, either physically by climbing their summits, or mentally by mastering the secrets of their structure—to *come* and *see*—yes, but also to *conquer* the grandeur of the Alps!

The intellectual conquest of the Alps, however, is not yet completed by geology, and this is the very fact which has restrained many of the veteran geologists abroad from attempting a popular book on the subject. Prof. Fraas published in 1892 a useful book called "Scenerie der Alpen," which erred in being too geological for the ordinary tourist. In 1894, the Committee of the International Geological Congress published a special "Livret-Guide" of Switzerland, wherein pedestrian tours are planned and described geologically by the best Swiss authorities on the various areas of the Alps. With these exceptions, Sir John Lubbock entered an open field, and has done so with considerable success.

The book numbers 473 pages, arranged in twenty-five chapters. About two-thirds of it are devoted to the *geological* causes, while one-third discusses the *physical* causes which have moulded the surface features of Switzerland.

It is perhaps rather unfortunate that the book begins with three such difficult chapters as those entitled "The Geology of Switzerland," "Origin of Mountains," and "The Mountains of Switzerland." In the opening pages the reader finds himself perforce initiated into the involved question of the origin of gneiss.

> "The foliation of Gneiss is probably of two kinds: the one due to pressure, crushing, and shearing of an original igneous rock such as Granite, the other to original segregation-structure" (p. 3).

A sentence like this cannot but be a stumbling-block to the ordinary reader. Granite, Serpentine, the Crystalline Schists, and the successive geological periods from Carboniferous to Miocene and Glacial time are briefly dealt with. The second chapter contrasts "Table Mountains" with "Folded Mountains," and demonstrates that the Swiss mountains belong to the latter class, having been "thrown into folds by lateral pressure." Geological terms—such as outcrop, dip, and strike; fold, fault, and fold-fault; anticline, syncline, slickenside, and cleavage are explained; various examples are also given of the dynamo-metamorphic changes induced in rocks. Attention is directed in the third chapter to the fact that the main longitudinal valleys (*e.g.* the Rhone-Rhine valley which cuts through Switzerland in the direction of the main axis, S.W.-N.E.) occupy the troughs of the mountain-folds, whereas the transverse valleys (*e.g.* the Reuss and Ticino in N.W.-S.E. direction) are independent of the folds, being "entirely due to erosion." Denudation of the surface is discussed, and the geological proofs are given of the former presence of an arch of sedimentary strata above the crystalline rocks of the central chain of the Alps. Three well-known geological sections illustrate the text—Schmidt's section from the Rhone valley at Viesch to the Averser valley in the Engadine, Favre's "Mont Blanc" section, and Heim's "Windgälle and St. Gothard" section. A computation "gives 4500 metres or, say, 14,000 feet, which erosion and denudation have stripped from the summits of the mountains!" (p. 66).

There follows a lighter series of six chapters on glaciers, valleys, rivers, and lakes. The physics of ice and ice-movement, and the characteristic features of glaciers are carefully described. Evidences of the "Former Extension of Glaciers" are considered, and abundant examples quoted of the influence which ancient moraines had in diverting the courses of rivers and damming up lakes. The chapter on "Valleys" leads us into some confusion of ideas. A "fault valley" is said to be "comparatively rare" (p. 143). The writer repeats the principle mentioned above, that cross-valleys are valleys of erosion, while longitudinal valleys are of geotectonic origin. But he then asks himself the question, "Why should the rivers, after running for a certain distance in the direction of the main axis, so often break away into cross valleys?" (p. 148). "Three possible explanations," suggested by Prof. Bonney, are given, and then the following passage occurs:—

> "Under these circumstances I have ventured to make the following suggestion. If the elevation of the Swiss mountains

[1] "The Scenery of Switzerland, and the Causes to which it is due." By the Right Hon. Sir John Lubbock, Bart., M.P., F.R.S., &c. Pp. 473. (London: Macmillan and Co., Ltd., 1896.)

be due to cooling and contraction leading to subsidence as suggested in page 34, it is evident, though, so far as I am aware, this has not hitherto been pointed out, that, as already suggested, the compression and consequent folding of the strata (Fig. 43) would not be in the direction of A B only, but also at right angles to it, in the direction A C, though the amount of folding

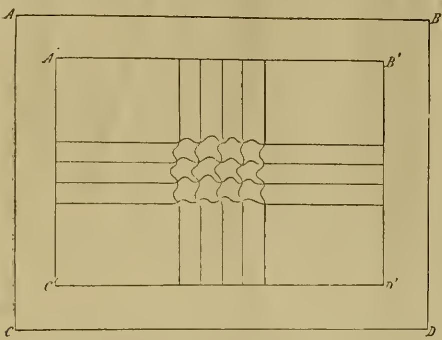

Fig. 43.—Diagram in illustration of mountain structure.

might be much greater in one direction than in the other. Thus in the case of Switzerland, as the main folds run S.W. and N.E., the subsidiary ones would be N.W. and S.E. If these considerations are correct it follows that, though the main valleys of Switzerland have been immensely deepened and widened by rivers, their original cause was determined by tectonic causes" (pp. 149, 150).

Thus the chief distinction previously made by the writer between longitudinal and transverse valleys is finally annihilated by his own suggestion that both may have had their primal cause in tectonic movements! But this idea finds by no means its first exponent in Sir John Lubbock. It is perfectly familiar throughout the writings of Austrian and German geologists. Take the following passage, which I translate from Rothpletz :—

"*As the youngest expression of the mountain-forming forces*, these (the transverse faults) have had a specially important influence on the present topography of the mountains, the direction of the flowing waters, and the origin of lake-basins. It is to them above all that the longitudinal synclinal folds of the Alps owe the outflow of their waters by transverse valleys; and the length of high ridges of rocks has been determined by them." ("Ein geolog. Querschnitt durch die Ost-Alpen." Stuttgart, 1894, p. 190.)

The stratigraphical facts observed by these geologists somewhat modify the theoretic suggestion of Sir John Lubbock. They prove that the transverse lines of weakness, whether of simultaneous origin or not with the longitudinal folding, were planes of movement long after the longitudinal folds had *ceased* to move, *i.e.* had become in technical language "dead" folds. *It is this relative youth of the transverse faults which has made them so often revolutionisers of Alpine drainage.* We would certainly have expected to have this important matter looked into by Sir John Lubbock, especially as he has devoted considerable space to minute matters of drainage in the three succeeding chapters on the "Action of Rivers," their "Direction," and "The Lakes."

With regard to the vexed question of the excavation of the lake-basins by glaciers, Sir John Lubbock states that "there are strong reasons against regarding glaciers as the main agents in the formation of the great Swiss and Italian lakes" (p. 210). The general reader may learn much from the chapter on "Lakes."

A very important subject is then introduced in Chapter x.—"The Influence of the Strata upon Scenery." If I may prophesy, this is the "coming" theme in popular geology. Combining as it does the interest of beauty of form with that of varied natural phenomena, it appeals alike to artist or tourist, geographer or petrographer, physicist, chemist, or geologist. This, I repeat, is at once the grandest, the most striking, and the most popular department of the Science of Scenery; and, what is more, the student of it would rightly choose Switzerland for his field of study in preference to any other country in Europe! Yet Sir John Lubbock has devoted only one chapter of twenty pages to this subject, and has treated it in a meagre, perfunctory manner. Only one sketch-section by Baltzer illustrates this extensive subject. The reader who brings enthusiasm to the book, and has Alpine pictures in his eye, will stir life into the bare facts, but the reader who has not will fail to be impressed.

All the subsequent chapters from xi. to xxv. are geological in their bearing, and take up the districts of Switzerland in turn. The geology of the Jura mountains is sketched in simple, clear style in Chapter xi. The Miocene and Glacial deposits of the "Central Plain" of Switzerland are described in Chapter xii. The next, entitled "The Outer Alps," is one of the best in the book. It runs easily along and describes, amongst other things, the geology of the ever-fascinating Rigi and its proud rival Mount Pilatus. One almost regrets that the chapter should be brought to its close in the cloud of controversy which overhangs the history of the "Klippen." The chapter on "Central Massives" is rather overladen with the opinions of many geologists, but concludes by regarding the Central Massives (1) "as an integral part of the general Alpine system, not as independent centres of upheaval; and (2) as complex systems of compressed folds" (p. 307).

Chapter xv., "The Lake of Geneva" is, like Chapter x., a sacrifice to science—useful, instructive, practical, but written with a marked economy of the imagination. Surely the most prosaic Englishman who has seen the view of the mountains from the northern side of the lake must remember it all his days, and feel the very words "Lake of Geneva" act like a charm upon him. This chapter in the "Scenery of Switzerland" commences as follows :—

"The Lake of Geneva is 45 miles in length, and about 10 in breadth. It is 375 metres above the sea, or 309 in depth.

"The bottom, moreover, is covered by subsequent deposits to an unknown depth, so that originally it was probably below, perhaps much below, the sea-level. Indeed, if the slopes of the mountains at Meillerie and Vevey (see Fig. 100) are continued under the bed of the lake, the alluvium must have a thickness of no less than 600–800 metres, which would make it 200–400 metres below the sea-level. The actual outlet at Geneva is in superficial débris, but the river comes upon solid rock at Vernier, 1197 feet above the sea-level, 33 feet therefore below the surface-level of the lake, and 951 above the bottom. It is, therefore, a true rock basin" (p. 308).

The same conclusion is arrived at in the same matter-of-fact way about other lakes, *e.g.* Lake of Neuchâtel (p. 259), Lake of Constance (p. 414). There are some graceful touches however :—

"The country about Vevey and Montreux is the Riviera of Switzerland. It is lovely now, but what must it have been before the monotonous terraces of the vineyards and the endless rows of vine bushes replaced the ancient forests of chestnut, birch, and beech; and the picturesque Swiss châlets were extinguished by whitewashed villas and gigantic hotels" (p. 310).

"The Massif of Mont Blanc," Chapter xvi., again falls distinctly short of the sublimity of the subject. Is it so necessary to begin with exact figures?

"'The Massif of Mont Blanc' is elliptical in outline, about 30 miles in length, and 10 in breadth, extending from S.W. to N.E. from the Col de Bonhomme, across the Valais at Martigny to the Dents de Morcles; the extreme N.E. portion being severed from the rest by the Rhone" (p. 322).

Again, why give the reader so little of Sir John Lubbock, and so much of other authors? De Saussure and Favre may indeed have "made" the geology of Mont Blanc, but why these long French quotations from their writings? Does the Pavillon de Bellevue stand in need of a testimonial to its beauty from any French writer, even Favre? (p. 327). A graver objection to Sir John Lubbock's treatment of the Mont Blanc massif is the inadequate account of its geotectonic relations. It is impossible to satisfactorily explain the "causes to which Mont Blanc is due," without setting forth its relations to the fold "trough" of the Briançonnais and the broken western end of the Valais "crest" of mountains. It is, indeed, the greatest blemish in Sir John Lubbock's book that he nowhere gives a geological insight into the structure of the Monte Rosa massif of mountains from the Simplon Pass to the St. Bernard. Yet this area is the Swiss frontier, whereas the Mont Blanc massif is almost wholly French and Italian. However fully, then, the succeeding chapter on "The Valais" treats the Rhone Valley, it misses its mark with regard to the mountains. The few notes on Zermatt and the Matterhorn, on p. 357, are quite insufficient.

The Bernese Oberland is more deftly handled than Mont Blanc. The intricacies of the overfold of gneiss are explained, and there are no fewer than six geological sections from Fellenberg and Baltzer to illustrate the fourteen pages. The Rhone, Upper Aar, Reuss, Ticino, and Rhine valleys are treated much after the fashion of the Swiss "Livret-Guide" referred to above, although without its daily itinerary. In these chapters we are made to feel that the author has himself gone over every step of the ground, but he follows the "Livret-Guide" too apparently in his geology. "Zürich and Glarus"—the title of Chapter xx.—gives an account of the variation in the movement of the old glacier which once filled the Lake of Zürich. The Glarus Mountains are described in accordance with Heim's well-known works. Chapter xxiv. on the Engadine is short. It explains the shifting northward of the watershed of the Alps, and the consequent formation of the line of lakes. The rocks of the Bernina, Julier, and Baselgia, are also indicated.

There are 154 illustrations in the book. Almost all are of the nature of geological sections or diagrams, 123 being reproductions from the works, mostly of Swiss geologists, and a few from English authors. The remainder are simple diagrams—with the exception of familiar photographs of the Rhone glacier, the Grimsel, and the valley of Chamonix; a successful photograph of the rock-fold at the "Cascade of Arpenaz," and another of a "Scratched Pebble" from the moraine at Zürich. Two figures specially deserve to be noted, Figs. 49 and 50, the front and side view of a river cone, as they, along with one or two drawings from Heim ("Bay of Uri," Fig. 141, and "Volcanic Group of the Hohgau," Fig. 138), and from Baltzer ("View near the Grimsel," Fig. 37, and "View of the Jungfrau," Fig. 124), are the only illustrations which present to the eye of the reader scenic effects in combination with geological or physical truths. Like the text of the book, the illustrations are too technical for a thoroughly popular book on "Scenery." On the other hand, if the book lacks in imagination and style, it is not wanting in valuable and trustworthy facts, and these may be enough for the utilitarian mind.

A standard work amongst us already shows what can be made of the "Scenery" of a country in the hands of a geologist who is gifted with an artist's feeling for nature, and is a master of style. I refer to Sir Archibald Geikie's "Scenery of Scotland." Without this, we might have demanded less from Sir John Lubbock in his "Scenery of Switzerland." As it is, he has conferred a boon on the travelling English public, and broken new ground in the literature of the Swiss Alps.

MARIA M. OGILVIE.

THE TOTAL ECLIPSE OF THE SUN.[1]

III.

TRONDHJEM, *August* 14.

SINCE writing my last notes, the eclipse has come and gone, and we are homeward bound, rather depressed but satisfied that the *Volages* and ourselves had done our duty, and that it was Dame Nature alone who was to blame.

Although on the 8th the weather in the forenoon was very fine and promising, towards the latter part of the day a change set in, and dark clouds came up.

Captain King Hall, who came over from the ship in the afternoon, soon detected what was wrong; there were two currents, an easterly and a westerly one, contending for mastery. This elemental war was watched with anxiety for two or three hours, and at times the weather chances improved, but later rain set in, and we could only hope against hope. It rained during our dinner-hour in the tent, an excellent one lent us by the War Department, kept dry under foot by a tarpaulin, and a deep trench outside cut in the peat. Lieut. Martin, the navigating officer, to whose constant care many of the admirable arrangements on the island were due, who had not only taken charge of the integrator, but who has *ipsissma manu* put up all three of the discs,[2] remained on shore and did the honours.

A dim memory of the Latin grammar suggested champagne as an accompaniment of the well-cooked provender, for were we not bound on the morrow to face not only the *ingens æquor*, but, if all went well, something still more awe-inspiring.

Dinner over, the process of filling up all dark slides with the plates for the morrow was accomplished by Lieut. Martin, Mr. Fowler, and Dr. Lockyer, after which it was suggested that we should turn in early.

The Rev. E. J. Vaughan, my son, and I occupied one of the army tents, while Mr. Fowler and Lieut. Martin had their stretchers placed in Kiö Town Hall, as the 6-inch hut had been called. Our last survey of the weather was not one to raise our spirits to any great extent, but we were still buoyed up by the observed fact that, as a rule, the early mornings, looking eastward, were moderately clear.

As we expected the *Garonne*, on her return from Spitzbergen, to anchor near our island some time in the early morning, we had arranged with the guard to light a beacon fire directly she was sighted, to show them our whereabouts.

At 1.30 my son took it into his head to take a stroll around outside; his attention was first drawn to the beacon burning brightly on the hill, and the four marines in their lammy suits standing by the side of it. Looming up very black and large, close to our island, was the good ship *Garonne*, before her time. It was not long before we received two nocturnal visitors, Captain Harry and Mr. Müller, who had come off to see about the day's arrangements. The weather was anything but pleasant, and their return to the ship was heralded by a downfall of heavy rain.

At 4 a.m. the parties, led by Captain King Hall, began to arrive from the ship, the first thing they did on landing being to make cocoa and breakfast. Mr. Thomas, in charge of the chronometer, and the readers of the thermometers, were the first to take their stations, and for these at the time of first contact the work began with the sky almost entirely covered with clouds, with narrow

[1] Continued from page 421.

[2] It may be worth while to state that the eye-pointers used in connection with the discs were impromptu affairs made by the ship's carpenter, but they promised to work well. There must be fine adjustments, because it is not likely that the point to be occupied by the eye will be calculated to an inch. For these adjustments, then, we have first a horizontal bar, on which hangs a vertical piece of wood about ten inches long, free to slide. On this piece of wood slides up or down a piece of brass carrying a pointer marking the place of the eye; this is brought into position at the beginning of totality by the amanuensis.

breaks near the sun's place, and wider ones near the horizon, a condition of things which relieved Mr. Fowler from his spectroscopic determination of the beginning of the eclipse.

Gradually everybody fell into their stations; the sketchers went up the hill, but there was no need for them to carry out their instructions to shield their eyes by turning their backs to the sun.

There had been no sun to adjust the siderostat, so it was clear that the 9-inch prismatic camera would in all probability not be employed. Still Dr. W. Lockyer stood by at the mirror to make final adjustments.

A few minutes before totality, the delicate crescent was seen dimly through one of the breaks. I watched it in the $3\frac{3}{4}$-inch for a minute or two, but the clouds closed up before the commencement. I gave it a little time, and then gave the signal, "Go," in order especially to start the 6-inch prismatic camera, as the important ten-

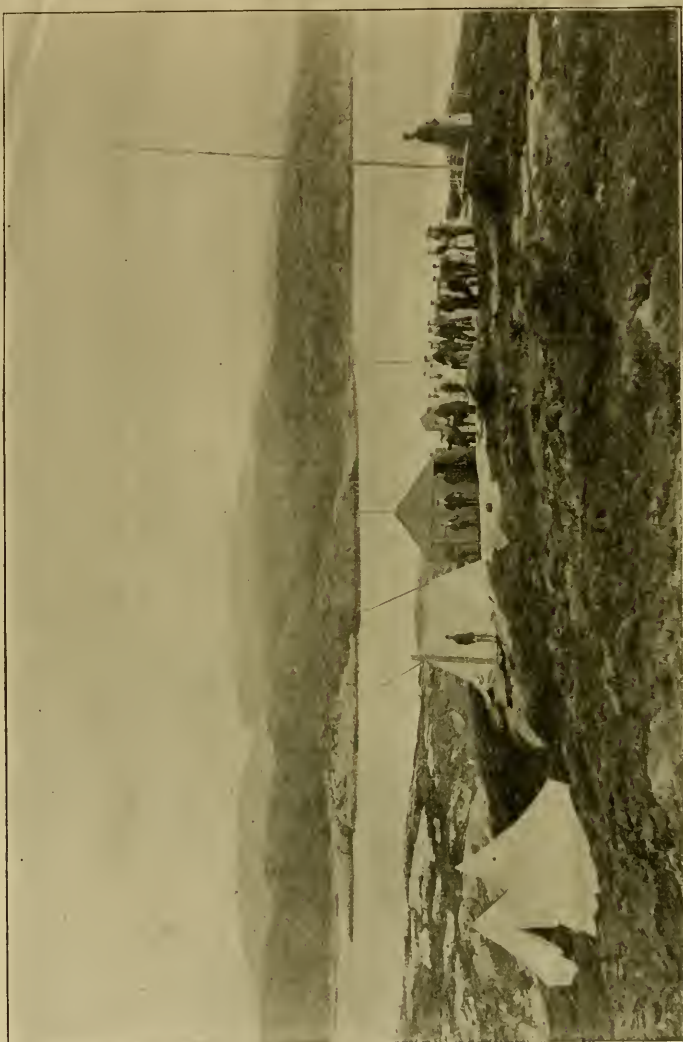

FIG. 9.—The Camp on Kiö Island, showing the Fiord and the Island and Land to the eastward.

seconds-before-totality-signal could not be given in the way agreed upon. All the photographic work, with the exception of the 9-inch, then went on as if the eclipsed sun were visible. The actual commencement of totality occurred shortly afterwards, the swoop of the shadow being almost felt. This instant was noted by Mr. Thomas amid a cry for lamps, especially from the time-keepers and some of the observers in the huts.

The time of the end of the eclipsed eclipse was also noted by Mr. Thomas, and the affair was over for most of us, although the colour observers and the meteorologists continued their notes till the fourth contact.

FIG. 10.—The Eclipse Observers. Photograph taken by Mr. Fowler immediately the Eclipse was over.

And then an unexpected thing happened. Captain King Hall called his men together, and, in a few admirably chosen words, expressed to me the regret of the *Volages* that such an important attempt to advance knowledge

had been frustrated. In reply, I told him that I thought an almost more important thing than the observation of a single eclipse had been accomplished. He had demonstrated that with the minimum of help, and that chiefly in the matter of instruments, such a skilled and enthusiastic ship's company as his could be formed in a week into one of the most tremendous engines of astronomical research that the world has ever seen; so that if the elements had been kind, all previous records of work at one station would have been beaten.

I added that I felt sure that the leaders of British science would thank him, his officers and men, for what they had done in aid of science when it came to be known, and further, that the kindness which the eclipse party had received on board the *Volage* had inspired a gratitude which it was not easy to express in words.

The party subsequently fell in to be photographed by Lord Graham and Mr. Fowler; then away to the ship for breakfast, and a curtailed Church service.

The repacking of the instruments was begun after breakfast, as the *Volage* was to rejoin the squadron the next day. Under these circumstances the Town Hall was left standing for the benefit of the friendly Lapps whose island we had invaded, but who seemed rather to enjoy our doings than otherwise. Talking of the Lapps, it would be interesting to know the Lapp mythology and folk-lore concerning eclipses. Immediately after totality, or rather so soon as it was light enough to render the channel separating Kiö from the island to the eastward clearly visible, we saw a large boat full of Lapps firing a *feu de joie*. The fact may be chronicled. I was all the more struck by it, as it seemed to be possibly connected with the Eastern custom to light fires to frighten away Rahoo, whose swallowing of the sun causes the eclipse.

. 11.—The 6-inch Hut, show ng Mr. Fowler and his Assistants at drill.

It seemed quite certain that the parties at Vadsö had fared no better than ourselves, and this was confirmed by the news brought by the *Calypso's* steam cutter in the afternoon. This cutter subsequently conveyed my son and myself to the *Garonne*, meeting her about a mile outside Kiö, and while the island was being rapidly left astern, full particulars were told me of all the camps which many of my shipmates had visited after the eclipse.

It was at Hammerfest that we first had news of any success, and that at Bodö. I had heard that there was a strong party of German astronomers at this place, but one of the fortunate ones, who subsequently came on board, told me, to my great regret, that there were no fixed instruments there at all, and that the photographs of the corona were taken with a small camera of the ordinary make.

Since my return home, it has been rendered evident that in inflicting upon us at Kiö so great a disappointment, Dame Nature was not really cruel, but was pointing a moral, namely, that in attempting to obtain records of eclipses, no stone should be left unturned in occupying every coign of vantage, however inconvenient or unpromising.

Hence she allowed a grand success to be scored at Novaya Zemlya, which would not have had a British observer within hundreds of miles had it not been for the chapter of accidents and the public spirit of Sir George Baden-Powell, who took a party there in his yacht *Otaria*. In this party was Mr. Shackleton, one of the assistants in the Solar Physics Observatory, who did such good work during the eclipse of 1893 in Brazil, and who, as already stated in NATURE, was hurriedly equipped after the larger eclipse instruments had been sent off.

It is on his results that I wish here to say a few words. I am sorry to say he is too unwell to give an account himself of his doings, but I have gathered from an article in the *Yorkshire Daily Post* that the voyage itself was by no means uneventful.

He left home on July 7, and joined the *Otaria* at Hammerfest, whence, after touching at Vardö, the party sailed for Novaya Zemlya, making for the Samoyede settlement of Karmakul, in the southern island. The intention was, after meeting some Russian astronomers, and obtaining information as to the navigation, to take up a point of observation some ten miles further south, in Gooseland, on the central line of the shadow-path. Although the party had not a very good chart—no trustworthy ones of these remote regions being published—they got into the bay on Bank Holiday Monday, and were going at a good speed—about ten knots—when the vessel gave three bounds and stood still, heeling over on her side.

The account continues:—

"Everybody hung on to something, for it was impossible to stand. Fortunately, however, the reef was only of soft rock, and it did little damage to the ship; only for four days we remained like that, about a mile away from the nearest land. We could not walk except by holding on to ropes, and had to get our meals on our knees or on the floor with cushions. After four days' hard work the sailors nearly emptied her, and pumped out all the drinking-water, and then at a high tide pulled her off."

It appears that

"The mishap arose from a little want of familiarity with the Russian cartography of these parts, which is naturally better than ours. It turned out that the soundings of the deeper portions were, so to say, in fathoms and the shallower in feet. A few of the deeper soundings having been verified by the lead, the rest were taken for granted, with the unpleasant result already detailed."

Still, in spite of this mishap, everybody working with a will, things were more or less ship-shape on the eclipse morning. There had not been many opportunities of adjustment, but, not unmindful of possibilities, I had taken the precaution of having every portion of the more important instruments adjusted, and each adjustment plainly marked before I sent it off.

Mr. Shackleton obtained twenty-one photographs with the prismatic camera, thirteen during totality, and five of the corona. I have already enlarged and begun to discuss these photographs, and I have seen enough already to be able to say that in my opinion the results obtained are of the highest possible value. In fact, we may almost say that the long-talked-of "flash" has at last been photographed. This brings a test to apply to contending theories, and there will be a good deal to be written about it later on.

It is not too much to say that "the winter of our discontent" at Kiö is turned into "glorious summer" by the sun of Novaya Zemlya!

I must not forget to add that the photographs of the corona, though they are of much lower value from the theoretical point of view, will be very useful in enabling the change in the appearances of the corona from eclipse to eclipse in relation to the sun-spot period, to be chronicled.

The *Yorkshire Daily Post* states that Dr. Stone, who also accompanied Sir George Baden-Powell, has obtained some photographs of spectra.

I must be permitted one other extract from Mr. Shackleton's statement, as it indicates the success of Sir George Baden-Powell's cruise in another direction, and is interesting as an account by an eye-witness of a most interesting event.

"After the eclipse we were busy repacking and getting all on board again. Our intention had been to go to the northern island to see about the safety of some stores which had been left there for Dr. Nansen, but we found it prudent to make direct for Hammerfest. Some of the Russian astronomers were about to make the attempt to cross Novaya Zemlya by means of dogs and sledges. . . ."

"At Hammerfest, on our return, we heard that Dr. Nansen had arrived outside, and as the steamship *Thor* came in and dropped anchor alongside, the intrepid explorer recognised Sir George, whom he knew well, and halloed, 'Hallo, Baden-Powell, is that you? I did'nt expect to see you here.' Our cutter was out, and at once Sir George was rowed off to the *Thor*. Dr. Nansen returned with him immediately, to the disappointment of the Norwegians, who were playing their National Anthem, and making other demonstrations in his honour. This was on Tuesday, the 18th. Mrs. Nansen arrived by express steamer, and the Doctor was very anxious to see her again. When she arrived there was an affecting scene. The reunion proved too much for the feelings of the faithful wife, who fainted away, and did not recover consciousness for a considerable time. Then came redoubled rejoicings. The people of Hammerfest were too much delighted to leave their countryman much opportunity of private happiness, and made a feast in the public hall. Dr. Nansen was very anxious about the *Fram*, though he felt quite confident that she would be coming in. 'It is only,' said he, 'a question of a week or two,' but at the same time he appeared disappointed that she had not preceded him. Our yacht took Nansen on to Tromsö, but I left her at Hammerfest to return by express steamer. The *Fram*, as you will have seen from the papers, turned in near Tromsö. When our steamer reached Tromsö the people there were very much disappointed that we had not brought Nansen back with us. At Bodö we learnt of the receipt of a telegram announcing that the *Fram* had returned, but at first were inclined to treat the news as a joke. It, however, turned out to be correct; so for the second time we hoisted all our flags and bunting in honour of the Arctic exploring party."

Fig. 12.—Lieut. Martin, R.N., setting up a disc.

Mr. Shackleton is loud in his acknowledgment of the kindness shown him by Sir George and Lady Baden-Powell, and they may, I think, rest assured that the scientific public of these islands, to speak of no wider territory, are grateful to them for their efforts in the cause of science. J. Norman Lockyer.

NOTES.

The Sanitary Institute has been holding its Congress at Newcastle-on-Tyne during the past week, and has got through a great deal of work. The Congress was opened on September 2 by the Duke of Cambridge, as President of the Sanitary Institute, after which the inaugural address was delivered by Earl Percy, the President of the Congress.

The steam-yacht *Windward*, with four members of Mr. Jackson's expedition on board, arrived in the Thames on Saturday. The yacht was the bearer of a voluminous mail from the leader of the expedition, some valuable maps, and several cases of scientific collections. The returned explorers, as was to be

expected, had a narrative of the highest interest to relate; but as this has been very fully reported by the daily press, we need do no more than report that Mr. Jackson has been able to confirm some of the more important discoveries of last year, and to produce a map of Franz Josef Land, which for the first time lays down with approximate accuracy its geographical outline, and at the same time entirely alters the previous records. Valuable botanical discoveries are reported to have been made, and numerous photographs taken of birds and beasts of the country in their native habitat and under ordinary conditions.

AFTER an absence of rather more than two years, Dr. Forsyth Major has returned to England from his scientific mission to Madagascar. His task was a very difficult one to perform, in consequence of the unsettled state of the country at the time of his visit, but Dr. Major seems to have succeeded in doing some solid scientific work. The explorer's collections have been deposited in the Natural History Museum, and include many specimens of *Æpyornis* bones from the marshes at Sirabé, and an extensive series of skins representing the recent fauna of the island. A fine collection of specimens of the flora of Madagascar, including four orchids reported to be new to science, has also been made.

DR. W. R. GOWERS will deliver the Bradshaw Lecture at the Royal College of Physicians on November 5. The title of the lecture will be "Subjective Sensations of Sound." The Lumleian lecturer for next year is to be Dr. Bastian, and Dr. Luff will be the Gulstonian lecturer. Prof. Sidney Martin is to deliver the Croonian Lecture in 1898.

ACCORDING to information brought by the steamer *Quiraing*, a severe earthquake (the severest since 1784, it is said) occurred in Iceland on the evening of August 26 and the following morning. Many farms at Hrepp, on the east coast of Iceland, two churches, and nearly all the farms in Hollum, Laudi, Kangaullum, Hollkrapp and Fgolshlid were destroyed, and sheep and cattle killed. Reykjavik, Bargarfjord and Hrulafjord suffered slightly. No lives seem to have been lost. The centre of the disturbance was apparently Hecla, where an eruption appeared imminent.

A REUTER telegram of September 2, from Yokohama, reported a disastrous earthquake in the north-east provinces of Japan on the evening of August 31. The town of Rokugo was entirely destroyed, and other towns were severely damaged. Many lives were lost. On the same day extensive damage was done in the southern parts of Japan by a typhoon.

THE death is announced of Mr. R. W. R. Birch, a hydraulic and sanitary engineer of repute. Mr. Birch had been for many years a member of the Council of the Sanitary Institute, and of the Royal Meteorological Society.

NEWS has come from Annemasse (Haute Savoie) of the death of M. Henri Aimé Résal, the mining engineer. M. Résal, who was the author of numerous books on mining mechanics, was a member of the Academy of Sciences, editor of the *Journal des Mathématiques Pures et Appliquées*, and President of the Société Mathématique de France. He was born in 1828.

THE death is recorded, at the age of seventy-three, of Prof. Egli, the geographer, who is perhaps best known for the "Nomina Geographica" which he edited.

THE new Gatty Marine Laboratory at St. Andrews, intended to replace the wooden structure in which Prof. McIntosh has worked for the past ten years, is to be formally opened on October 8. Its more noticeable features will be a tank-room 30 feet square, and a research-room of the same dimensions. The latter is being fitted to accommodate six workers.

THE fungus foray of the Yorkshire Naturalists' Union, which has now been for several years an annual event, is to take place this year at Selby, from which as a centre excursions are to be made to various woods in the East and West Ridings, on September 19, 20, 21, and 22; the members of the party meeting each evening at the "Londesborough Arms," to compare notes and arrange the fungi gathered. On Monday evening, September 21, a conference will be held, at which papers will be read by Rev. Canon Du Port, Mr. George Massee, Mr. Carleton Rea, and Mr. Harold Wager, and in illustration of their remarks a lantern will be provided by Mr. W. Norwood Cheesman. Mr. A. Clarke will exhibit a number of stereoscopic photographs of fungi, and microscopes will also be provided. Mycologists who may wish to attend will be heartily welcomed, and circulars will be sent on application to Mr. W. Denison Roebuck, Sunnybank, Leeds, or to Mr. W. Norwood Cheesman, The Crescent, Selby.

A BLOCK of granite bearing the following inscription has, says the *Academy*, been recently placed on the southern shore of the Lake of Sils in the Engadine:—"In memory of the illustrious English writer and naturalist, Thomas Henry Huxley, who spent many summers at the Kursaal Hotel, Maloja."

It is announced that the Royal Society of Canada has resolved to commemorate the five-hundredth anniversary of the first landing of Cabot in North America by holding a meeting at Halifax from June 20 to 26 of next year, and to erect, at a cost of not less than £200, a monument at Sydney in Cape Breton.

NOTICE is given in the current number of the *Journal of the Society of Arts* of two prizes offered by the Society. One is the "Fothergill" of £25 and a silver medal, for a paper on "the best means of effectually preventing the leakage of current to earth in electrical installations from generating heat and setting buildings on fire." The paper should consist of about eight thousand words, and be written with a view to being read and discussed at an ordinary meeting of the Society. Papers submitted for the prize must reach the Secretary by October 1 of this year. Each paper must be type-written, and bear a motto, the name of the writer being enclosed in a sealed envelope with a similar motto. The other prize announced is a gold medal and the sum of £20, and is to be bestowed, under the terms of the Benjamin Shaw Trust, "for any discovery, invention, or newly-devised method for obviating or materially diminishing any risk to life, limb, or health, incidental to any industrial occupation, and not previously capable of being so obviated or diminished by any known and practically available means." Descriptions of the inventions of intending competitors must reach the Secretary of the Society of Arts not later than December 31, 1896.

THE Sanitary Institute has just issued a list of its twenty-second course of lectures and demonstrations for sanitary officers and students. The course, which is to be commenced on Monday, September 28, by a lecture, by Mr. Wynter Blyth, on "The Education, Status, and Emoluments of Sanitary Inspectors," has been arranged for the special instruction of those desirous of obtaining knowledge of the duties of sanitary officers, and of others desirous of obtaining a practical knowledge of sanitary requirements and regulations. The lectures will be delivered at the Sanitary Institute, London, and the introductory lecture is to be free.

CAPTAIN ROBERTSON, of the Dundee whaling vessel *Active*, which has just returned from a voyage to the Arctic regions, has, says the *Times*, forwarded to Mr. Dickson, of Oxford, the result of certain observations made, at the request of the latter, during the cruise, together with samples of the water through which the *Active* sailed. The observations were taken with a view to

ascertaining the distribution of food fishes in relation to their physical surroundings; and the samples of water brought home number 130, taken from the sea each day at noon, the surface temperature and other particulars having been noted. It is understood that the results of the inquiries will be communicated to an international congress of men of science interested in this and kindred questions.

AN account of an interesting plant which has the apparent property of turning its leaves in a north and south direction, thus behaving like the needle of a compass, is given in *Garden and Forest*. Mr. E. J. Hill, of Chicago, who seems to have been investigating it, gives the name of the plant as *Silphium laciniatum*, and says that the *Silphium terebinthinaceum* is affected in the same way, seventy-five per cent. of the latter orienting themselves in the manner mentioned above. The tendency to orientation seems to be a function of the ages of the leaves in question, the younger ones being said to point more accurately north and south than those of greater age, the latter falling off and therefore supplying an insufficient amount of evidence. It is mentioned that Sir Joseph Hooker remarked the uses which might be made of the peculiarity of this plant; it is stated, also, that he was able when travelling to note perfectly the change in direction of the train by observing the general appearance of these plants which were scattered over the plain.

IN consequence of the great number of earth movements that occur in Turkey and on the boundary of the Ottoman Empire, the Meteorological Observatory of Constantinople had been charged to make a study of them. The first year's observations were begun on January 1, 1895 and the director, Dr. Agamennone, has given in the *Bulletin* some details of the results obtained. The mean number of movements per day amounted to over two, the total number amounting to 753, and out of these 400 had been observed in Turkey, 236 in Greece, and 56 in Bulgaria. Tabulating these movements in order of their magnitude it is shown that the small ones are the most frequent, amounting to 519. The moderate ones are 225 in number, while the remaining 9 have resulted in large calamities. The importance of this new branch will be demonstrated when the observations extend over a larger period of time, as certain marked indications, which appear to precede large disturbances, will be more fully studied. In this way warnings may be eventually given of disturbances likely to do damage.

The current number of *Kosmos* (No. 606) gives the results obtained by Mr. Eginitis of the velocity of the earth-wave during the earthquake at Constantinople. Employing the method of Dutton and Hayden, he finds that the depth of the centre of disturbance was 34 kilometres, a distance not very different from that obtained by Mr. Lecomte. The velocity of the wave he found to be between 3 and 3·6 kilometres per second, a value equal to that found for the progress of the wave movement in the last earthquake at Locride. Mr. Eginitis reminds us of the seismic period which two years ago affected the eastern part of the Mediterranean, Zante, Thebes, Locride, Constantinople, and Sicily, without mentioning some of the minor movements in Europe and Asia. These countries lie nearly in a straight line.

IN the *Comptes rendus* for August 17, M. Berthelot gives an interesting account of some recent explorations of the copper mines of Sinai, the most ancient workings mentioned in history. These mines were worked by the Egyptians from the time of the third dynasty (about 5000 B.C.), and were abandoned about 3000 years ago owing to the poorness of the deposits and their distance from Egypt proper. The ores consist of turquoises, containing about 3·3 per cent. of oxide of copper, and sandstone impregnated with carbonate and hydrosilicate of copper, the metal forming two or three per cent. of the rock. The minerals were carefully sorted and fused with oxide of iron and carbonate of lime in crucibles made of quartzose sand cemented by clay. The furnaces were built of sandstone, and the fuel used was wood. Both fuel and carbonate of lime must have been brought from some distance. Some of the slags consist largely of $2FeO.SiO_2$, with the addition of crystals of magnetite; others are less basic, and contain lime. It is remarkable that the existing fragments of furnaces and crucibles, the slags and the scoriæ contain the same products, and show the same characteristics as those in modern smelting-works, and that the general method of extracting the metal differed little from that still employed in the treatment of similar ores. At a time when weapons of wood and stone were used by the Egyptians the copper must have been highly prized by them; moreover, the hand-labour of slaves cost little. The continuous working of such poor deposits need not therefore occasion surprise.

THE Vienna correspondent of the *Times* states that an interesting report of its first year's work has just been issued by the Austrian State Institute for the preparation of anti-toxin serum. Of 1100 cases of diphtheria treated with the serum, 970 recovered, a very favourable result compared with the previous mortality. When the remedy was applied on the first and second day of the illness, the percentage of deaths was only 6·7. After the third day, however, the mortality reached 19 per cent., rising to 33 per cent. after the sixth day. Of 318 cases of preventive inoculation only twenty were attacked by the disease, mostly in a mild form, and all recovered.

THE winter session of the medical schools and colleges in the United Kingdom will open at the beginning of next month, and in connection with many of the institutions an address or a lecture will be delivered by a prominent medical man. We glean from the *British Medical Journal* the following information respecting the opening arrangements of most of the schools:—St. Bartholomew's Hospital College session will begin on October 1, when (or on the succeeding day) a dinner of past students will be held in the great hall of the hospital. Charing Cross Medical School will re-open on October 5, on which day, at 4 p.m., Prof. Michael Foster will, as has already been stated in these columns, deliver the first Huxley lecture on "Recent Advances in Science, and their bearing on Medicine and Surgery." At the opening of the St. George's Hospital School, on October 1, an address may be expected from Mr. W. Adams Frost. In the evening of that day the annual dinner of past and present students will take place at the Hôtel Métropole. The winter session of Guy's Hospital Medical School will begin on October 1. The biennial festival dinner of the school will be held the same evening at the Hotel Cecil. The London Hospital Medical College will re-open on October 1, and in the evening the annual dinner will take place in the college library. An introductory address will be given at the opening of the session of St. Mary's Hospital School, on October 1, by Mr. Morton Smale. The school's annual dinner will be held at the Holborn Restaurant on the same day. At the Middlesex Hospital School Dr. W. Essex Wynter will, on October 1, deliver an address, and past and present students and others will meet for dinner at the Café Royal in the evening. At the school in connection with St. Thomas's Hospital the prizes will, on October 2, be distributed by the Lord Justice Lindley, and in the evening former and present students will dine together at the Whitehall Rooms. The session of the Faculty of Medicine of University College will commence on October 1, when Prof. Sidney Martin may be expected to deliver an introductory address. Past and present students will meet for dinner in the evening at the Hotel Cecil. Dr. Wills will deliver an address at the re-opening of the Westminster Hospital Medical School, and the prizes will be subsequently delivered by Archdeacon Furze. The annual

dinner will take place in the evening of that day at the Westminster Palace Hotel. Mr. Jonathan Hutchinson will, it is announced, deliver an introductory address at the opening of the session at the Owens College on October 2. At University College, Liverpool, the session will commence on October 1, on which date Sir William O. Priestley will distribute the prizes. Mr. Victor Horsley has consented to open the session of the Medical Department of the Yorkshire College, on October 1, with an introductory address; he will also distribute the prizes. The winter session of the Queen's Faculty of Medicine, Mason College, will commence on October 1; so also will the sessions of the College of Medicine, University of Durham, and the Sheffield School of Medicine. At Durham, the scholarships and prizes will be distributed by the Bishop of Newcastle; and at Sheffield, Sir Henry Littlejohn will deliver an introductory address.

The current issues of the *Lancet* and the *British Medical Journal* are almost wholly devoted to information likely to be of service to those who are students, or who are about to become students, in one or other of the medical schools of this country. The *Chemist and Druggist* for September 5 contains articles and details specially written for the future chemist and druggist.

Mr. Edgar Thurston, Superintendent of the Government Museum, Madras, has, with the assistance of Mr. T. N. Mukerji, prepared a copious index to the valuable "Dictionary of the Economic Products of India," by Dr. G. Watt, a review of which appeared in our columns of November 1, 1894. Those who have to refer from time to time to Dr. Watt's great work will, we have no doubt, be grateful to the compilers of the present volume. It is issued from the office of the Superintendent of Government Printing, Calcutta.

The Sub-Committee charged with the reception of the British Association have done a very excellent work in compiling an interesting handbook to Liverpool and its neighbourhood, entitled "A Scientific Handbook to Liverpool," a work which, though mainly intended for the benefit of those attending the meeting, will possess a considerable value after the meeting is over. We do not know to whom the happy idea originally occurred, but are probably not far wrong in attributing it to Prof. Herdman, who certainly undertook the duties of editing and general arrangement, and has carried them out very happily. The various authors by whom he has been assisted are not only peculiarly qualified to deal with the subjects severally treated, but each has apparently been solicitous to collect a mass of details which will save any one interested in a similar research a great amount of time and trouble. We have only space to give the bare titles of the several chapters; but this is of the less consequence, as the little book, it may be hoped, will find its way into the hands of all intending visitors. Mr. W. H. Picton, able to draw on the work and research of his father, deals with history and antiquities; while Mr. G. H. Morton is responsible for the notes on the geology of the district. Dr. Forbes, of the Liverpool Museum, treats of the vertebrate fauna; Prof. Herdman reserving to himself the marine fauna. Mr. W. E. Sharp and Mr. R. Brown share the entomological and botanical interests. Mr. Plummer gives statistics connected with the climate of Liverpool and Birkenhead; and Dr. Oliver Lodge contributes an article on the Mersey and its tides. The article on the Docks and the principal engineering features of the city is jointly produced by Prof. Hele-Shaw and Mr. Percy Boulnois, the city engineer; while Sir W. Forwood treats of the city's trade and commerce. The history of the chemical industries is entrusted to Dr. Kohn. This list of names amply justifies the remark that each section has been entrusted to the authority best qualified to deal with it. An appendix supplies some useful information concerning the Isle of Man, where it is proposed to hold a subsidiary meeting at the conclusion of the Liverpool meeting properly so called. Five maps are included in the book—a geological map of the district, a biological chart of the Irish Sea, a chart of Liverpool Bay, a geological map of the Isle of Man, and a chart of the sea round the southern extremity of the isle, including the biological station at Port Erin. Such a book cannot but add greatly to the interest of the meeting, and afford much valuable instruction not only to the members of the British Association, but also to the inhabitants of Liverpool, who must have often felt the want of such a handbook. It is issued for the British Association by Messrs. Philip, Liverpool.

In addition to the above-mentioned guide-book, the British Association has issued, also through Messrs. Philip, an "Excursion Guide Book," in which is to be found just the information likely to be of interest and use to those taking part in the numerous outings arranged; and being partly the work of leaders of the excursions, and under the editorship of one of the local secretaries of the meeting, its contents may be thoroughly depended upon.

The additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*, ♀) from West Africa, presented by Mr. F. Wyville-Thomson; two Garnett's Galagos (*Galago garnetti*) from Mombassa, East Africa, presented by Rear-Admiral Rawson, C.B.; a Brown Capuchin (*Cebus fatuellus*, ♀) from Guiana, presented by Miss Cissie Wade; a Suricate (*Suricata tetradactyla*, ♀) from South Africa, presented by the Rev. Wilfred Fisher; an American Black Bear (*Ursus americanus*, ♂) from Vancouver Island, presented by Lieut. Bryan Godfrey Faussett, R.N.; a Llama (*Lama peruana*, ♂) from Peru, presented by the executors of the late Colonel J. T. North; a Moorish Tortoise (*Testudo mauritanica*), a Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mrs. Fraser; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mr. Hugh Mytton; a Brown Capuchin (*Cebus fatuellus*, ♀), a —— Bell Bird (*Chasmorhynchus*, sp. inc.) from Guiana, three Painted Terrapins (*Clemmys picta*) from Nova Scotia, deposited; a Long-tailed Glossy Starling (*Lamprotornis æneus*), two Yellow-backed Whydah Birds (*Coliopasser macrurus*, ♂ ♀) from West Africa, purchased.

OUR ASTRONOMICAL COLUMN.

New Comet.—A telegram from Kiel announces the observation of Comet Giacobini on September 4 last, at 8h. 44m. Nice mean time. Its position was then R.A. = 17h. 10m. 30s., Declination = $-7°\ 29'$. The given movement per day is 1·8m. in R.A. and 0'·25 in declination, so that the comet should be looked for soon after sunset, the above position being about 22° due south of α Herculis, making also a very obtuse isosceles triangle with ζ and ν Ophiuchi. Another telegram gives particulars of a second observation of Comet Giacobini at Nice, on September 6, 8h. 26·5m. Its position as observed was R.A. = 17h. 14m. 16s.; Declination = $-7°\ 49'$. The comet is noted as very feeble.

Comet Brooks (1896).—A telegram received from Kiel announces the observation of this comet at Geneva on September 4, at 10h. 0m. It was then in R.A. = 13h. 30m.; Declination = $+55°\ 40'$. This gives a position admirably suited for observation, being about 2° due east of ζ Ursæ Majoris. The motion of the comet is eastward. Another observation of the comet has been made at Lick Observatory. Its position as seen there on September 6, at 11h. 56·5m., was R.A. = 13h. 51m. 44s.; Declination = $+55°\ 25'$. The motion per day is 6·5m. in R.A. and 36" in Declination, the general direction being easterly. No mention is made of the appearance of the comet.

Telegrams to "Astronomischen Nachrichten," No. 3376.—We gather the following information from the current number of the above journal. Prof. Holden, writing from Mount Hamilton, dated August 11, says: "A telegram just received from Schaeberle says that the sky was wholly clouded at his eclipse station in Japan." Mr. Lowell telegraphs from his observatory at Arizona on August 31: "Companion Sirius re-discovered by Dr. See. Angle 219°. Distance 5"·9." Prof.

Pickering telegraphs, also on September 1, from Cambridge, Mass., to the following effect: "Bailey at Arequipa finds μ' Scorpii spectroscopic binary. Period 35h."

THE PLEIADES.—Some time ago, we gave an account of several legends and myths connected with that most interesting cluster of stars, the Pleiades. These myths were, for the most part, gathered from an article which appeared in *Globus* (Bd. 64, p. 362). It seems, however, that our stock is by no means complete, for Dr. Heinrich Samter, in the current number (Bd. 70, p. 176) adds considerably to it. We make this reference for those readers who take a special interest in folk-lore, and would wish to look up this article.

METEORS TRANSITING THE SOLAR AND LUNAR DISCS.—What apparently appear to be unique observations, recorded quite recently in America, are given in the current number of the *Revue Scientifique*. It seems that during the night of July 21 and 22 last, Mr. William Brooks, the director of the Smith Observatory at Geneva (New York), saw all at once a round dark body pass slowly before the bright disc of the moon, the latter being almost full. The apparent diameter of the body is given as about one minute, and the duration of its transit amounted to three or four seconds, its direction being from the east towards the west. The second observation was made about midday on August 22, by Mr. Gathmann, an American astronomer, but the place of observation is not stated. He saw a meteor pass before the solar disc, occupying a period of time amounting to eight seconds in its transit. It is suggested that this body is one of a great number which circulates round our planet; it does not seem at all necessary to assume that our earth is the centre of attraction, indeed it seems rather improbable, as the observation would then, no doubt, be more common. Our present idea of space is that it is a meteoritic plenum, and full of bodies traversing through it at various speeds and at various distances from us, so that the chances of making such an observation, especially at periods of shooting-stars, is not altogether impossible, but is likely to occur, provided the observer is fortunate and happens to watch a comparatively slow-moving meteor.

THE GREAT SEISMIC WAVE OF JAPAN.

FULL particulars of the terrible wave which devastated the coast of Japan last June, causing the destruction of 20,000 lives and 12,000 houses and other buildings, have recently been given in the daily papers. The official report made to the Japanese Government having now reached this country, it may be interesting shortly to summarise the particulars of this occurrence, and to give the causes which have been assigned for its creation; and also to refer to waves of a similar character that have occurred on former occasions and in other localities.

The wave appears to have originated at a short distance from that part of the coast of Japan which trends in a north-easterly direction from the northern part of Sendai, midway between Tokio and the island of Yezo or Hokkaido. From Kiukasan, the northern island of the Archipelago, the coast is fjord-like in character, abrupt mountain ridges running down almost to the water edge. In the bays and estuaries that interrupt the shore line several important towns and many fishing villages were situated; with a few exceptions these have all been destroyed. The distance over which the effect was felt has been variously given as extending over a length of coast of from 200 to 300 miles.

Suddenly, almost without warning, between eight and nine o'clock in the evening of the 15th, three successive waves, the highest estimated as being fifty feet in height, swept over the land bordering on the coast, and in a space of a few minutes had caused a frightful devastation of property and the death of nearly all the inhabitants. There was nothing to presage the disaster or give warning. The barometer gave no indication of anything abnormal in the atmosphere. About half an hour before the catastrophe three or four shocks of earthquake were felt—not violent shocks, but of the vertical kind, which are known to be dangerous. Shortly afterwards a booming sound came from the direction of the sea. At first the noise was only like that of a coming gale; rapidly it increased until the sound assumed the volume and din of artillery; then in a moment three successive waves, varying in height from twenty to thirty feet, came rolling on the shore. In a space of time of about two minutes these waves had accomplished their fearful work of devastation and ruin.

Beyond the destruction of life and property some remarkable incidents occurred. At Kamaishi one wave came curling round the land-locked bay from the left in a semicircle, meeting another wave, which came in from the right, and before the waters could recede a third wave came in from the centre. In five minutes the town was wiped out. Temples, houses, and vessels lying in the bay, were alike swept away, broken up and destroyed. A large two-masted schooner of 200 tons was left lying almost uninjured five hundred yards inland, in the centre of what had been a wheat field. Another had its bows stove in, its stern post and rudder carried away, its deck ripped open, and the planking of its sides broken in short lengths. Altogether nineteen schooners and junks were cast ashore, In one place, men swept out to sea from one side of a bay were thrown up alive on the opposite beach; and in another case, several persons were deposited on an island nearly three miles from the town whence the wave had carried them.

The disturbance was not felt at sea at any great distance from the shore. Fishermen engaged in their occupation near the centre of the disturbance off the coast of Shizukawa heard, as they supposed, the booming of big guns in the distance; looking seawards they saw the surface of the ocean heave in huge masses, which, after rising to a great height, broke in the middle and swept northward and southward, striking the coast with a deafening roar. The waves passed under the boats without swamping them, but the water in the vicinity of the shore remained so rough throughout the night that the fishermen could not make the land until the morning. In other parts fishermen, plying their trade four miles from the coast, on returning to shore in the early morning after the catastrophe, received the first notice of what had occurred; others, engaged three miles out in the same locality, encountered heavy breakers rolling from the north. A steamer which left Hakodate in the morning of the day of the disaster, and must have been near the scene of the calamity at the time it occurred, experienced nothing out of the common; and other passing steamers reported only an abnormal current.

The Japanese Government have self-recording tide gauges fixed at various parts of the coast. The three nearest stations to the scene of disturbance are situate at Ayukawa, in the Oshiaka district; at Hanasaki-mura, in the Hanasaki district; and at Misaki-Machi, in the Miura district in Choshi Bay. At the first station the sea had been calm all the day of June 15. Suddenly at 8.25 p.m. the water fell 7·9 inches; five minutes after it rose 4·59 feet; and after an interval of five minutes had fallen down again. After this there occurred a succession of waves at intervals of about four or five minutes. At 11 p.m. the height of the wave, as indicated on the gauge, was 6·56 feet; the difference between the maximum and minimum height of the waves being 8·86 feet. After this the water gradually subsided to the ordinary sea-level.

At the second station, at 8.50 p.m. the water fell 3·28 feet, followed by five or six disturbances in an hour. After this an accident to the gauge prevented any further record. At 8.10 the next morning, when the gauge was visited, the sea had become calm.

At the third station some small waves began to show at 8.40, their height being 7·90 inches, and occurring at intervals of five minutes, gradually decreasing in height until the normal condition was obtained.

From these records it appears that the influence of the wave was greatest at the north station, and that an interval of twenty minutes elapsed before the gauge at the southern station was affected.

The effect of this seismical disturbance of the crust of the earth was sensible all over its surface, so far as may be judged from the records of instruments thousands of miles distant. On June 15, the day of the earthquake at Japan, at about 8.30 p.m., Prof. Vicentini, in Italy, noted the commencement of the disturbance on the seismograph, and a similar disturbance was recorded on the instrument at Shide, in the Isle of Wight.

As to the cause of the disaster, Prof. John Milne, in an article in the *Geographical Journal*, states his opinion that this was due to a seismic, rather than volcanic origin. The disturbances which have occurred in this locality have been, without exception, confined to the eastern sea-board of Japan, where the land suddenly sweeps downward beneath the deep Pacific. Along the line of

this submarine slope, which forms one of the longest and sharpest contours on the surface of the earth, earthquakes are frequent. Some opinions have been expressed that the disturbance had its origin in a sudden collapse of the sides of the subterranean crater known as the Tuscarora Deep, a triangle-like depression off the north-east coast of Japan, which has a depth of 4665 fathoms, or over five and a half statute miles. This deep, however, lies too far away from the supposed site of the generation of the wave. The kind of disturbance that probably occurred in the bed of the ocean may be illustrated by what happened on land at Bandai-San in 1886. Here millions of tons of earth and rocks were hurled in a given direction with such force that an enormous wave of solid material traversed a distance of many miles at great velocity. Any similar disturbance happening at the bottom of the ocean might fully account for what took place on the coast of Japan in June last. The earthquake which took place in Japan in 1891, the shock of which was so great as to be sensible in Europe, resulted in a fracture upon the surface of the earth for a distance of from forty to sixty miles. The ground, which on one side rises from 4000 to 6000 feet, was lowered relatively to that on the other side from 20 to 30 feet; river-beds were compressed, and valleys narrowed by the lateral movement.

That great submarine earthquakes result in the change of the ocean bed, is well known to those who have charge of cables near volcanic regions. It has been ascertained that when a cable has been broken at two points, the soundings have shown that there has been so great an increase in the depth that it has been necessary to select a fresh line for the cable in order to avoid the site of the disturbance. That the movement originated in the bed of the ocean, is evidenced by the fact that deep-sea shell-fish were found stranded on the high ground swept by the waves; and that in one place the fishermen found their nets floating on the surface upside down, they evidently having been cast up by the submarine disturbance.

Ever since the ninth century records exist of earthquake-waves which have devastated these coasts, but in no case have the results been so disastrous as on this occasion. The great earthquake-wave of 1891 caused the loss of life of over 7000 persons.

The exact locality of the disaster extends from the island of Kinkwa-San on the south (N. lat. 38° 15′, E. long. 141° 30′) to Hachinohe on the north (N. lat. 40° 30′, E. long. 131° 30′), the coast here assuming a convex shape. Between these points nearly every town and village were visited by the wave. The general direction of the wave appears to have been north by east.

Of previous examples of earthquake-waves, that due to the Lisbon earthquake of 1755 is matter of history. This wave rose to a height of forty feet in the Tagus, leaving the bed of the river dry as it rolled inwards. It was experienced at sea 120 miles west of St. Vincent, shaking vessels so violently that men were thrown from the deck; and its effect reached as far as this country, the water rising from eight to ten feet on the coast of Cornwall.

In 1868, and again in 1877, earthquake-waves rolled over the coasts of Peru, causing great devastation and loss of life. On the former occasion the U.S. warship *Watteree* was thrown up on the coast and carried inland one and a half miles; the second wave, in 1877, carrying it inland a still further distance. These waves, originating at a distance of about 9000 miles, off the South American coast, took nearly twenty-four hours before their effect reached the coast of Japan, where they rose and fell at intervals varying from ten minutes to half an hour, alarming the inhabitants and causing them to fly to the high land.

The volcanic upheaval at Krakatoa, in 1883, shook the whole of Java, and the sea-wave inundated the coasts of that country and Sumatra, causing a loss of 36,000 lives. The lava, mud, and ashes from this eruption darkened the air for fifty miles, and reddened the light of the sun for months after the catastrophe. The coast-lines were altered, and peaks on which lighthouses had been erected disappeared.

Several instances were given in NATURE of March 7, 1895, of earthquake-waves having been encountered by vessels at sea; and again, in November 10, 1895, of an earthquake-wave which burst on the shores of Madeira in 1891.

In January 1894, the *Normania* (of the Hamburg-American line), when 750 miles out from New York, encountered one of these waves. A stiff gale which had been blowing had moderated, and, while the vessel was running at full speed, an enormous wave was observed "masthead high" coming forward like a solid wall, and reaching as high as the bridge, wrecking the upper-deck-house, containing the music-room, ladies' room, and officers' quarters, and injuring several of the crew.

Numerous other instances could be quoted of these waves, which are frequently erroneously called "tidal waves," but which no doubt have their origin in some volcanic disturbance in the bed of the sea.

THE AMERICAN ASSOCIATION MEETING, 1896.

THE forty-fifth annual meeting of the American Association took place from August 24 to 29, at Buffalo, at which town it has now met four times, and although one of the smallest attended of recent meetings, seems to have been a very pleasant gathering. In most of the Sections full complements of communications were presented, notably so in those devoted to Chemistry, Botany, Geology, Anthropology, and Physics. The arrangements, a programme of which has reached us, appear to have been made with great care, and evidently no pains were spared to ensure the success of the meeting. Space will not permit us to print the addresses of the retiring President and Vice-Presidents; suffice it to say that they well sustain the standard of merit fixed by previous deliverances.

The retiring President, Mr. Edward W. Morley, took as the subject of his address "A Closed Chapter in Science." He spoke of the investigations into atomic weights of elements, in reference to their mutual relation so long supposed to be expressed in integrals in accordance with Prout's hypothesis. This hypothesis is now seen to be erroneous, so that it marks a closed chapter. The careful and repeated investigations of Morley himself and of others for many years, but mainly during the decade since the last Buffalo meeting, have proved that the ratio of atomic weights of hydrogen and oxygen, for instance, can only be expressed by a fraction, and is very nearly that of 1 to 15·88; it cannot possibly be that of 1 to 16. The same result has been found for many other elements with sufficient accuracy to establish the conclusions finally, and beyond the possible limits of error.

Mr. Carl Leo Mees, Vice-President of Section B (Physics), spoke on "Electrolysis and some associated Problems in Molecular Dynamics." In Section C (Chemistry), Mr. W. A. Noyes took as the subject of his address "The Achievements of Physical Chemistry." Mr. F. O. Marvin, in Section D (Mechanical Science and Engineering), discoursed on "The Artistic Element in Engineering." The subject of the address of Mr. B. K. Emerson, before Section E (Geology and Geography), was "Geological Myths." Section F (Zoology) was addressed by Mr. Theodore Gill on "Some Questions of Nomenclature." In Section G (Botany) the address was by Mr N. L. Britton on "Botanical Gardens." Miss Alice C. Fletcher spoke to Section H (Anthropology), on "The Emblematic Use of the Tree in the Dakotan Group"; and Section I (Social and Economic Science) was addressed by Mr. Wm. R. Lazenby, on "Horticulture and Health."

It will have been noticed that no mention is made in the foregoing list of Section A (Mathematics and Astronomy); but we are informed that Mr. Wm. E. Story, the Vice-President of the Section, was not present at the meeting, and his proposed address was not received, and could not therefore be delivered. The Vice-President of Section F (Zoology), instead of speaking, as he intended, on "Animals as Chronometers for Geology," spoke on nomenclature.

A commemorative meeting was held in recognition of the sixty years of professional work of Prof. James Hall. Prof. Hall was present at the meeting of the Association, as was another founder of the Association, Dr. Charles E. West, of Brooklyn.

Three founders of the Association have died within a few months, viz. Bela Hubbard, Thomas T. Bouvé, and Josiah D. Whitney.

The nominating Committee have presented the name of Wolcott Gibbs for President, and they recommend that the next meeting be a merely formal one, to be held at Toronto, August 17, 1897, to welcome the British Association for the Advancement of Science.

Among the business transacted was a resolution deprecating legislation against vivisection; while another favoured the metric standard of weights and measures, and recommended further legislation to secure its adoption.

APPLICATION OF RÖNTGEN RAYS TO THE SOFT TISSUES OF THE BODY.

WHEN the photographs which accompanied Prof. Röntgen's original paper were reproduced, the question was frequently asked, Shall we ever be able to photograph every part of the human skeleton? The developments have been very rapid, and now that it has been demonstrated that we can practically photograph the whole human skeleton in life, and throw shadows of a great portion of it upon fluorescent screens, we wonder the question was ever raised. It was quite natural that a similar demand should spring up for further extension of the art, so that other tissues than the osseous might be revealed by the same methods. Like many other observers, I early satisfied myself that we could examine and photograph certain organs within the cavities of some of the lower animals, such as the frog, rabbit, fish, &c. Further, in a considerable number of photographs of the deeper-seated structures, faint shadows of the human body were now and then obtained indicating the position of certain muscles, fasciæ, and even organs like the heart itself. While experimenting, like others, with the object of overcoming the difficulties of photographing the skeleton, I made a series of observations with a view to testing how far it would be possible to obtain photographs, or shadows upon fluorescent screens, of the contents of the three great cavities of the human body as well as the surrounding osseous walls. So far these experiments indicate promise of future development, and a few photographs are here reproduced, more by way of showing what may yet be accomplished than as an evidence of what has already been done.

In placing the following statements before the readers of NATURE, I desire to emphasise the importance of combining the study of the physical with the purely medical aspect of the question. To begin with, whatever progress may in the future be made with Röntgen rays, it must be remembered that the discovery itself came from the physical laboratory. Naturally, in the advancement of the study, certain aspects of the question will be more easily overcome by those familiar with normal and pathological tissues; others will just as naturally fall to be investigated by those engaged in physical research. Of course no line of demarcation can ever be drawn between these two, and the physician or surgeon who desires to pursue the subject must to a certain extent be conversant with physical science. On the other hand, the physicist will require to make himself somewhat familiar with the needs of those engaged in the study of animal and vegetable tissues. In this paper, therefore, while demonstrating some of the earliest examples obtained in this newer branch of the art, I desire to point out wherein we need the aid of those engaged in the physical laboratory. In so doing, I shall refer for the most part to the examination of the soft tissues of the human body, although it must never be forgotten that the use of Röntgen rays is not limited to any one part of the animal kingdom, and, further, that the structures in the vegetable kingdom are also being investigated by its means.

In attempting to photograph the soft tissues of the body, it might be thought they offered so little obstruction to the passage of Röntgen rays as compared with the bones, that less force would be required to demonstrate their presence. In other words, the natural suggestion was that if the bones of the extremities were to be photographed with certain apparatus in a given time, by diminishing the exposure we might be able to catch the soft tissues before they disappeared. This, of course, is true to a certain extent, and, in a certain number of my experiments, I was able, by carefully judging the exposure, to photograph not only the bones themselves in disease, but the fleshy parts, and this with such accuracy that the surgeon could see the internal pathological change and the external configuration of the part as well on the same plate. But when it came to the examination of the organs of the body, it was found that the rule did not apply as might have been expected, and instead

FIG. 1.—Pelvis of lad with femora, &c.

of a less force it became evident that we would require more force. For example, in one successful attempt to photograph the lungs of the frog, I was able to demonstrate their presence and a deposit in one of the lobes of the right side, and this with an ordinary Paget plate, the exposure only being something like the time represented to give twenty successive flashes of the tube due to twenty interruptions of a mercury interrupter with a current registering ten volts and ten ampères across the terminals, the spark being about six inches, and the focus tube one of Newton's small earliest pattern. In this case, however, the

tube was removed six inches from the animal. Those familiar with this work will immediately see that, considering the difference in size of the human body, a tube placed at that distance could not possibly give the same result on a plate or fluorescent screen. To begin with, we know that there is a definite relationship between the distance at which the photographic plate is removed from the object to be photographed on the one hand, and the distance between the object and the Crookes' tube on the other. In other words, to get anything like sharp definition it becomes necessary to remove the tube to a considerable distance, which means of course loss of power, and consequently more difficulty in seeing objects on a fluorescent screen, and a longer time in exposing a plate. The distance must vary in given cases, and experience, after careful experiment, in the present state of our knowledge can only determine at what distance the tube is to be placed, although we very often get a valuable suggestion by first examining an object on the fluorescent screen, and noting the distance of the tube from the object.

FIG. 2.—Coin impacted in gullet of boy aged six.

But another difficulty has now to be considered. Suppose we wish to try to photograph the heart. The patient must be placed on his face so that the organ may be as near the photographic plate as possible, and naturally the spine and other organs which we do not wish to be photographed will be between the object and the Crookes' tube. On the other hand, if we wish to photograph the spine, it may be necessary to omit the tissues of the heart and lungs. A still better example may be found in the case of the head, where the rays have to pass through the whole of the cranium, and yet the surgeon may desire to photograph the inside of only one side of the skull. Again, with renal calculus we do not wish to photograph the intestines lying in front, nor the muscles of the back behind. Fortunately the construction of the focus tube helps us in this way, and in an earlier number of NATURE of this year I pointed out a method by which this might be accomplished. The Röntgen rays springing from the platinum anode diverge from a point, consequently if we place the tube near the right side of the head, and the photographic plate on the left, the shadows caused by those structures immediately next the tube are so diffuse that they scarcely appear on the negative, while a sufficient number of the rays still pass through to photograph the part of the head which is in contact. By carefully arranging the tube therefore, one may photograph the heart, sternum and ribs by the same method; and if the patient be placed on his back, lying on the sensitive plate, these structures will be omitted, but the spine will be photographed. We can, also, by the same method photograph any part of the skull at will. Considering what has been said in the previous paragraph, it might be here argued that, seeing we are placing the tube near the body, less power will be required; but if we reflect in the case of the abdominal, thoracic, and cranial cavities, there is such density of tissue to overcome that we are more than ever in need of greater energy.

Following out these indications, I made a series of experiments and observations upon the apparatus at my disposal, and came early to the conclusion that more powerful currents would be necessary. Instead of measuring these in the usual way by the length of the spark of the coil, I placed Lord Kelvin's cell tester and ampère-meter in the circuit with a rheostat, so as to control the current at will, and taking a large German coil, in which the wires were thicker than the English form, the currents were gradually increased up to nearly thirty ampères. The experiments were pushed to such an extent that the focus tubes would not stand the molecular strain, and for this reason, at the instigation of Dr. J. T. Bottomley, several strands of wire were fused in the end of the tube bearing the kathode, while the anode was made adjustable so that the platinum might be removed at any distance from the kathode until the maximum result was obtained. There must be a relationship between the amount of energy passed into the coil, on the one hand, and the force coming out from the focus tube after being transformed. In other words, the coil is simply a transformer of a certain amount of energy which gives rise to conditions within the tube, which again give rise to X-rays. It was evident I had pushed this to the limit of the present make of tube. The question will naturally here suggest itself to those familiar with the subject, Is it necessary to use such currents, or could we not do with less energy by properly economising the force in the transformer and vacuum tube? The question is a very proper one, as all experimenters know that some tubes will give better results than others with a certain amount of force passed through a particular apparatus. This is yet to be settled, as well as the questions involving the amount of current absolutely necessary; the best form of coil; whether the coil itself is the best kind of transformer; and lastly, and probably most important of all, the conditions of the tube itself, and they all afford examples of what has been previously stated about the further need for physical research. What is here meant by the above statements is simply: with the apparatus as it stands at present, to get certain results, one is

forced to use greater currents than might have been expected. But throughout the experiments, either upon fluorescent screens or in photography (I do not meantime enter upon the question of whether the maximum luminescence on the screen is the proper condition for obtaining the best result on the sensitive plate), the conditions were kept as nearly as possible uniform. In a previous paper in NATURE, I pointed out the advantage of a good interrupter, emphasising in attempts at instantaneous photography the value of the mercury form; but whether we use the latter or render the screw of the Apps' coil more tense so as to get larger sparks, any one watching the effect upon the ampère-meter and the fluorescent screen at the same time, will soon appreciate how important it is to control the current by means of the rheostat throughout the experiment. I have made experiments upon different kinds of glass for tubes; different sized kathodes; thicknesses of anodes; various materials for the latter; tubes have been sent to me by Mr. Friedrich, with a request that they might be compared with English forms; the Berlin Electrical Company have also placed their tubes at my disposal, but after many trials I know nothing so important as the constant attention to the vacuum throughout the exposure. Some of the best photographic results in the deeper structures of the body were obtained by the small and earliest form of Newton's tube. Another method of control is to place the two poles attached to the secondary coil at a certain distance from each other. This, of course, is used in testing the length of the spark before beginning the experiment. If these be too near during the exposure the sparks fly across, and the current being short-circuited the tube is cut out, but when the space is increased the tube becomes luminescent. This distance should be noted, and may be used to control the amount of electricity passing through the tube, as alteration in the vacuum causes the sparks again to fly across. By means of the spirit-lamp or Bunsen burner a little heat applied to the bulb at once corrects the vacuum, and a certain uniformity of condition within the tube results.

It may here be pointed out that in using fluorescent screens for the deeper structures of the body, barium-platino-cyanide in some instances gives a better result or a darker shadow than the potassium salt. I am quite aware of the fact that the potassium is more luminous, and it may be that it is a matter of construction of the screen or the particular specimen employed, because samples of these salts vary in their effects. After using a large number of different materials I, like others, have fallen back entirely upon the potassium or barium salts, but employ both, and the barium has the great advantage of being a good practical agent well suited for hospital purposes, and durable. I have still in my possession a screen made of this salt early in March of this year, and, although small in size, it gives as good results as any of my newer screens. I find a darkened room for medical purposes much better than any form of cryptoscope. Under favourable conditions many parts of the face and head can be distinctly seen on the screen. In some instances I have seen foreign bodies, such as shot in the scalp; in another I was able to differentiate, in a case of paralysis of the extremities, between fracture of the skull with pressure on the soft tissues from the effusion of blood and obstruction due to a star-shaped fracture, as opposed to the diagnosis of a bullet which was thought to be situated at a particular spot. The tissues of the neck may easily be searched for foreign bodies which obstruct the rays. Photographs of all these can of course be obtained, and I need hardly point out that, in the present state of our knowledge, the photographic plate reveals in some instances what the screen fails to show. There is one curious exception to this, where the movements of the organ are rapid, such as in the heart, because this necessarily interferes somewhat with success owing to the movement during the exposure of the plate. Passing to the chest, the outline of the pleural spaces may be seen, and in one case condensation of the apex of the lung was thrown as a shadow upon the screen. The heart itself as a body in motion, the ascent and descent of the diaphragm, the liver covered with the diaphragm, can also be made out. The majority of those conditions have been photographed as well as observed, and I have a series of pictures showing enlargement of the heart, enlargement of the liver, and in one case renal calculus. It need hardly be said in addition that every part of the trunk and extremities, as far as the osseous parts are concerned, have been photographed. I do not use fluorescent screens in photography, one amongst other reasons being that the plates used were much larger than any screen in my possession.

While these statements seem to indicate considerable progress in the art, I desire expressly to interpret them in the light a surgeon or physician would view them, lest any misconception should result. When one reads of instantaneous photography, direct inspection or photography of so many of these tissues, it may be argued that we have now brought the subject to a thoroughly practical issue; but it is not so. For this reason I have placed these statements before your readers, in the hope that those engaged in the physical research may know how much we are yet in need of their aid. Take the statement of rapid or instantaneous photography; a careful perusal of the valuable summary in the pages of NATURE for April 30, shows that this statement is applied to the extremities for the most part. It need hardly be pointed out that what the surgeon desires is instantaneous photography of every part of the body, particularly where there is movement. Further, the reader may imagine that in seeing the movements of the heart, one can examine it much as the physiologist does the beating of the same organ in the frog during dissection; but it is not so. Before the movements of the diaphragm and heart, the limits of the pleural cavities, and

FIG. 3.—Thorax and upper extremities (adult), faint shadows of viscera.

the pathological changes in the tissues of the same, can be of great value to the physician, much more has yet to be done. The serious investigator is more impressed with what has yet to be done, than elated with what has already been accomplished. It is with great pleasure that I read in the columns of NATURE of the continued advances of those well fitted to engage in the study of the properties of Röntgen rays in the physical laboratory; and while we have reason to be pleased that the rays have been clearly proved to be of great value in the diagnosis of certain affections, every part of the apparatus must be investigated and improved upon before we obtain thoroughly satisfactory results. JOHN MACINTYRE.

SCIENCE IN THE MAGAZINES.

PROF. H. F. OSBORN, curator of vertebrate palæontology in the American University of Natural History, New York, contributes to the *Century Magazine* a popular account of prehistoric quadrupeds found in the Rockies during the past few years,and to be exhibited to the public at that museum in October. Interest in his description is greatly increased by nine remarkably fine illustrations (reproduced from water-colour drawings by Mr. Charles Knight), designed to give an idea of the animals as they probably appeared in life in their natural surroundings. Another interesting article in the *Century* is made up of extracts from the journals of the late Mr. E. J. Glave, whose journey to the Livingstone Tree had such a melancholy termination. On July 8, 1894, Mr. Glave reached the tree beneath which Dr. Livingstone's heart is buried. Jacob Wainwright, the Nassick boy who read the burial service, cut on the tree the words: "Dr. Livingstone, May 4, 1873. Yazuza, Mniasere, Vchopere." The body was roughly embalmed and carried to Bagamoyo, on the coast opposite Zanzibar, afterwards to be taken to England and buried in Westminster Abbey. As to the tree, Mr. Glave wrote in his journal: "Although done twenty years ago, the inscription is in a splendid state of preservation. The tree shows no disfigurement, and, moreover, the carving is not on the bark but on the grain of the tree itself. It is a hardwood tree, three feet in diameter at the base; at thirty feet it throws out large branches; its top is a thick mass of foliage. When Livingstone died the heart and other viscera were buried beneath this tree, and the bark was cleared off for a space of two and a half feet square; in this space Jacob Wainwright (whose account my discovery verifies to the letter) carved the inscription with no dunce's hand, the letters being well-shaped and bold. The tree is situated at the edge of the grass plain, and is very conspicuous, being the largest tree in the neighbourhood. It is about five miles south south-west from the present site of the village of Karonga Nzofu, an important Bisa chief, whose father was a friend of Livingstone. Chitambo's is now ten miles away. It was originally near the tree; in fact, Livingstone died a few minutes' walk from the old village of Chitambo." The tablet which Mrs. Bruce—the daughter of Livingstone—sent out by Captain Bia and Lieut. Franqui to commemorate the explorer's death, was put up by them eight miles from the spot where he died, and was afterwards carried off by the chief of a slave caravan.

"There is scarcely a modern skull preserved in our great anatomical museum beside those of abnormal malefactors. There is no fairly representative collection of the variations of our race; and there is no means of learning the characteristics of it in contrast to those of other races. This is far more the case in other directions; any solid comparative study of man's framework is as yet utterly impossible. Of many races not a single skeleton is preserved; and those of which we know a little are only shown by a few scanty specimens, of which the history and details are scarcely ever recorded. Of both past and present races a collection of at least a few dozen specimens of each race, precisely dated and localised, are the smallest amount of material which would enable us to begin a scientific treatment of the varieties of man." So writes Prof. Flinders Petrie in the *National Review*; and he suggests that, to systematise the study of man, a large museum should be established where examples of every object of human workmanship can be preserved. He is sanguine enough to think that this great repository of the works of man will be realised in the course of a few years. Such an institution would undoubtedly be of service to science. From this proposal of Prof. Petrie's, ethnologists may profitably turn their attention to a paper on "African Folk-Lore," contributed by A. Werner to the *Contemporary*. While staying for some months in East Central Africa, the authoress collected a number of traditional tales of the Mangánja, and she now relates them. Many of these stories deal exclusively with animals; and all of them proceed on the assumption that animals, human beings, and inanimate objects feel and act in much the same manner. There is a striking similarity between these myth-stories and the stories of "Uncle Remus"—a fact which goes to confirm the opinion that the latter originated with the African.

Prof. Ray Lankester reviews Mr. Archdall Reid's speculations on "The Present Evolution of Man" in the *Fortnightly*. "Mr. Reid," he says, "seems to be under the impression that the lines, or rather two of the lines of the present evolution of man have been definitely and satisfactorily indicated by his speculations. I am far from admitting that he has done more than demonstrate and draw attention to some tendencies of that evolution. . . . I am by no means convinced that the present and future evolution of man is being determined exclusively or even mainly in the simple way and by the obvious factors which he has placed before us."

Two editorial notes in *Scribner* deserve mention. In one a plea is made for the adoption of the metric system throughout the United States. The Bill introduced last session, and which will again be brought before Congress in the coming session, provides for the substitution of the metric system immediately in practically all the departments of the Government of the United States, and the adoption of the metric system of weights and measures as the only legal system to be recognised after the first day of January, 1901. The second note referred to is on Summer Schools, or vacation courses. It appears from a report of the U.S. Bureau of Education, that more than three hundred vacation courses, dealing with all branches of knowledge, are now held at various educational centres throughout the world.

In the *Strand Magazine*, Sir Robert Ball, continuing his series of astronomical articles, describes the discovery of Neptune, his treatment of that well-worn subject being illustrated with several interesting pictures. A number of reproductions from curious photo-micrographs form the chief feature of Mr. W. G. FitzGerald's article on "Some Wonders of the Microscope" in the same magazine. There is also a story dignified as an "Adventure of a Man of Science," which has for its scientific foundation the cure of madness by mysterious capsules. Even this flimsy basis is better than the description, in last month's *Strand*, of the use of a camera to obtain a photograph, by means of Röntgen rays, of a stolen diamond inside the thief's body. We should have thought it was known by this time that cameras are not used in Röntgen photography. Sir C. H. T. Crosthwaite shows a little better acquaintance with the subject in a story entitled "Röntgen's Curse," contributed by him to *Longman's*. The central figure of the story concocted a liquid which, when painted on the insides of his eyelids, made him as perspicaceous as a platino-cyanide screen excited by Röntgen rays. The capacity thus gained proved anything but a source of enjoyment to the experimenter. The idea may be good enough for a story, but a cautious man of science would have tried his wonderful liquid on one eye, and not on both.

In the *Sunday Magazine* there are two popular articles of interest to naturalists: one describes and illustrates sculptures of animals adorning a number of ecclesiastical buildings; and in the other Mr. C. J. Cornish writes on nightingales' nests, his account being illustrated by photographs from life.

Chambers's Journal has, as usual, several popular articles on science.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. H. R. NORRIS, Mathematical and Science Master of Ipswich Grammar School, has been appointed Head-master of Barry Intermediate and Technical School, Glamorganshire.

THE Finance Sub-Committee of the Bradford Corporation recently held a special meeting and decided to allocate the following grants under the Technical Instruction Act:—Bradford Technical College, £2875; Free Library, £300; Boys' Grammar School, £500; Girls' Grammar School, £100; Mechanics' Institute, £300; School Board, £1000; Church Institute, £100; Blind Institute, £50.

THE Holiday Courses of Lectures delivered last month at Jena are reported to have been a great success. The lectures were grouped as follows :—(*a*) Natural Science, including Astronomy, Botany, Physics, Zoology; (*b*) School Hygiene, Physiological Psychology, Philosophy, Pedagogics; (*c*) Conversational German, Literature, History. The attendance at the courses was better than at those of last year's gathering, no fewer than 108 being present, representing thirteen nationalities. Seventeen of the students were English.

THE Committee of Technical Instruction, in their annual report to the Oxfordshire County Council, remark "that the District Committees have in most cases carried out their duties in a satisfactory manner. Those District Committees who have availed themselves of the assistance of the Parish Councils have found the benefit of so doing, as they have been able to get into closer touch with the needs of each parish." The wisdom expressed in the last paragraph seems obvious; yet we are afraid the hint needs to be repeated to other than the District Committees located in Oxfordshire. The report in question tells of much good work accomplished.

THE Report of the Governing Body of the Battersea Polytechnic for the years 1893–94–95 contains much information of a gratifying character. During the period the institution has been open—some two years—not less than 6000 individual students have attended its classes. The sum of £67,840 has been raised; the Polytechnic is in receipt of its full endowment, and is now in its third educational session, with a regular attendance of 2850 students. In accordance with the provisions of the scheme, and the requirements of the chief industries of the neighbourhood being borne in mind, it was, at the outset, decided that the initial work of the Polytechnic should consist of (*a*) evening classes for young men and women in technology, science, art, domestic economy, music, commercial and general subjects, with provision for gymnastics and other recreative and social work; (*b*) day schools for boys who have passed through the elementary schools and desire further education of a technical and scientific character; (*c*) Saturday classes of an advanced character for teachers. Success all along the line seems to be the summing up of the report.

THE British Consul-General at Frankfort, in the course of his latest report, quotes certain official information supplied to the Italian Government in regard to the cost of University study in Germany. To obtain the degree of Doctor of Law at Berlin costs 1300 marks, and for a Doctor of Medicine about twice that sum. The details are as follows :—Fee for matriculation, 18 marks; fee for examination for the medical faculty, 242 marks; diploma fees for the law faculty, 335 marks; for the faculty of medicine, 440 marks; fees for all lectures necessary to pass the various examinations in the law faculty, 400 to 500 marks, and in the medical schools, 800 to 1200 marks. To these must be added 150 marks for printing the candidate's dissertation, 300 marks for books for a law student, and 500 marks for the books and instruments of a medical student. These, of course, do not include the cost of living. For a law student who studies in a town where his parents do not live, 5000 marks must be allowed for board, lodging, and clothing during his course, and 7600 to 8000 marks for the 4½ years of a medical student's course. The cost of a civil engineer's course, including that of living, is estimated at 6000 marks for four years. At other German Universities the cost would be somewhat less, but the difference would not be very great, for the main item—the cost of living—is very much the same in all University towns. Foreign students often prefer the smaller Universities, especially those in South Germany.

A RECENTLY published Parliamentary paper shows that out of the funds entrusted to the Board of Agriculture for educational purposes in Great Britain during the financial year ended March 31 last, sums amounting to £7850 have been distributed in specific grants to eighteen institutions named. Since the first grant made by Parliament in 1888 the sums have increased from £2930 to £7850. These sums are divided under two main heads—general agricultural education under collegiate centres, including dairying and experiments (this item has increased from £200 to £6100); and special and provisional grants, which have decreased in eight years by nearly £1000. Major P. G. Craigie, Director of the Intelligence Division, who has drawn up this report for the President of the Board, says that considerable local efforts are now being made to make up for the conspicuous lack of educational facilities among the agricultural community of Great Britain to which the inquiries of the Departmental Committee of 1887–88 directed attention. The grants awarded were to the following eight collegiate centres in England and Wales :—University College of North Wales, Bangor, £800; Yorkshire College, Leeds, £800; Durham College of Science, Newcastle-on-Tyne, £800; University College of Wales, Aberystwith, £800; University Extension College, Reading, £700; University College, Nottingham, £450; Cambridge and Counties Agricultural Education Committee, £400; South-Eastern Agricultural College, Wye, £150; to the Eastern Counties Dairy Institute, Ipswich, £300, and the British Dairy Farmers' Association £300—in each of these two cases for dairy instruction; and to the Bath and West and Southern Counties Society £350, for special cheese and cider research and agricultural experiments. This brings the total for England and Wales to £5850. The remaining £2000 is distributed in Scotland thus :—Two collegiate centres, Glasgow and West of Scotland Technical College £650, and University of Edinburgh £550; University of Aberdeen, for agricultural instruction, £150; Scottish Dairy Institute, Kilmarnock, for dairy instruction, £300; the Highland and Agricultural Society, £100, and the Aberdeen Agricultural Research Association, £100—in both cases for agricultural experiments; and the Royal Botanic Garden, Edinburgh, £150, for instruction to working foresters and gardeners.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, August.—"The Thames run dry," by the Editor. It is less than 200 years since men walked across the bed of the river, near London Bridge; but the old bridges were almost like weirs in the obstruction offered to the flow of the water. The various dates since the year 1114 are given, the last being September 14, 1716. In this year, owing to a long drought and a strong westerly storm at the time in question, the Thames lay perfectly dry above and below bridge, with the exception of a very shallow channel, and many thousand people are said to have passed it on foot.—The first use of kites in meteorology, by A. L. Rotch. It has been stated that the first use of a kite in connection with meteorology was by Dr. Franklin in his experiments on atmospheric electricity in 1752; but Mr. Rotch points out that Dr. A. Wilson, of Glasgow, explored the temperature of the higher regions by raising a number of paper kites, with thermometers appended, in 1749. An account of one of the experiments is contained in *Trans.* Roy. Soc. Edin., vol. x. part 2. This method was successfully employed on several occasions in that and the following year.

Wiedemann's Annalen der Physik und Chemie, No. 8.—Contact electricity, by W. Nernst. The author formulates a theory of contact electricity based upon ionic velocities. Both ions of an electrolyte must diffuse equally rapidly, as otherwise an enormous accumulation of electricity would take place. The unequal velocities due to the unequal mobility of different ions must be compensated by a potential difference $\frac{dP}{dx}$. Hence the equation

$$U\left(\frac{dp}{dx} + c\frac{dP}{dx}\right) = V\left(\frac{dp}{dx} - c\frac{dP}{dx}\right),$$

where U and V are the mobilities of the anion and kation, p the osmotic pressure, and c the concentration of the solution.—Bolometric investigations of the absorption spectra of fluorescent substances and ethereal oils, by Bruno Donath. The measurements were made with a quartz prism, and all lenses were replaced by mirrors. It was found that the fluorescent bodies uranine, eosene, fluoresceine, æsculine, and chlorophyll show no absorption of the thermal spectrum down to wave-lengths of 2·7 μ. A chlorophyll solution 3·2 mm. thick has a region of strong absorption extending from the visible band in the red to the green rays. This region cannot be detected by the eye alone.—Emission spectrum of a black body, by Willy Wien. The author endeavours to reduce the number of hypotheses at the basis of the present theories of radiation. He also utilises Maxwell's theory of the distribution of velocities of molecules, but otherwise obtains his results on purely thermodynamic lines.—The new elements in cleveite gas, by J. R. Rydberg. This is an attempt to disentangle the spectrum of the supposed third new constituent of the gas from cleveite. The author calls

it "parhelium" (Pa) and assigns to it an atomic weight of about 3.—Distance action of the force of absorption, by W. Müller-Erzbach. The author claims to have proved that the absorptive force exercised, say, by iron oxide upon carbon bisulphide vapour is capable of acting across a thin layer of a substance like water or glycerine which is perfectly neutral itself. This molecular force is, unlike that of ordinary molecular attraction, capable of action at distances not exceeding 0·0025 mm. across intervening bodies.—Röntgen rays, by Otto Müller. In the course of an attempt to produce diffraction of X-rays, a shadowgraph of wire gauze was obtained under a metallic cylinder which screened the plate from the action of the rays. The distance between cylinder and plate was 20 cm. The author interprets the observation as a proof of the turbidity of the air to some at least of the X-rays, and ascribes the effect to diffusion.

Bollettino della Società Sismologica Italiana, vol. ii., 1896, No. 2.—New methods for geodynamical investigations, by G. Grablovitz. A valuable description of the instruments erected in the geodynamic observatories of the island of Ischia, including various forms of levels, horizontal pendulums, instruments for measuring the vertical movements of the ground, and seismoscopes.—New form of continuously recording seismometrograph, by A. Cancani.—On the so-called presentiment of earthquakes by animals, by A. Cancani.—On some facts resulting from microseismic observations, by G. Vicentini. A reprint of a paper already noticed in NATURE.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 31.—M. A. Chatin in the chair.—The Perpetual Secretary announced the death of M. Henri Résal, member of the Section of Mechanics.—On the subject of prime numbers, of which any given number cannot be a primitive root, by M. de Jonquières.—External characters and modes of distribution of the small tubercles or tuberculoids of the Leguminosæ, by M. D. Clos. A morphological study of the tuberculoids on the roots of nine sub-species of the Papilionacæ. In the two other groups of the Leguminosæ Cæsalpiniæ and the Mimosæ, the presence of the tubercles is by no means so frequent as in the Papilionacæ.—Memoir on the Law of Newton and on some problems in general mechanics, by M. E. La Combe.—On the effect of systematic errors in levellings of precision, by M. Ch. Lallemand. It is shown that, with a few exceptions, levellings of precision are subject to systematic errors, which may vary from ·05 mm. to 0·3 mm per kilometre, and hence are of more importance than the accidental errors to which, up to now, attention has been chiefly directed. It has not been found possible to connect these systematic errors with the particular instruments employed, with the observers, with the nature of the ground, or with the atmospheric conditions.—On a class of propositions analogous to the Miquel-Clifford theorem, by M. Paul Serret.—The deflection of the X-rays behind opaque bodies, by M. E. Villari. A gold-leaf electroscope, placed in the cone of shadow of a sheet of lead, was found to be discharged by the X-rays at rates which showed that the shadow was deepest at the centre.—Researches on the double chlorides, by M. R. Varet. A thermochemical study of the double chlorides formed by mercuric chloride with other chlorides.—Action of the soluble oxidising ferment from mushrooms on the phenols insoluble in water, by M. E. Bourquelot. The two naphthols are oxidised by this ferment in a manner that may serve to distinguish them, α-naphthol giving a violet colouration, β-naphthol a white precipitate, which dissolves to a yellow solution in ether.—On the freezing-point of milk, by MM. Bordas and Génin. Fifty samples of milk gave freezing points varying from $-0°\cdot44$ C. to $-0°\cdot56$ C., and the conclusion is drawn that the determination of dilution with water by cryoscopy is neither simple nor certain.—On the organisms causing disease of the silk-worm, by M. J. M. Krassilschtschik.—A telegraph cable attacked by Termites, by M. E. L. Bouvier.—On the secretory nerves of the trachea, by M. V. Thébault.—On the conjugation of the zoospores of *Ectocarpus siliculosus*, by M. C. Sauvageau.—On the velocity of sound, by M. G. W. Pierces.—On the resolution of the general equation of the fifth degree, by M. L. Mirinny.—On the geographical situation of submarine islands, by M. Reilly.

GÖTTINGEN.

Royal Society of Sciences,—The *Nachrichten*, Part 2 (Mathematico-Physical Section), 1896, contains the following memoirs communicated to the Society:—

April 25.—On the theory of automorphic modular groups, by R. Fricke.—On an optical effect of an electric field conditioned by the dependence of the dielectric coefficients on the strength of the field, regarded from the standpoint of the electromagnetic theory of light, by F. Pockels.

May 9.—Researches from the Göttingen University Laboratory (IV.), by O. Wallach. (1) Condensation-products of cyclic ketones, and syntheses within the terpene group; (2) a bicyclic ketone $C_{14}H_{22}O$; (3) benzylidene-methylhexanone $C_7H_{10}O:CHC_6H_5$; (4) dibenzylidene-methylhexanone $C_6H_5CH:C_7H_8O:CHC_8H_5$; (5) benzylidene-menthone; (6) benzylidene pulegone; (7) dibenzylidene-suberone $C_6H_5CH:(C_7H_8O):CHC_6H_5$; (8) dibenzylidene-methylpentanone $C_6H_5CH:C_8H_6O:CHC_6H_5$.—On the principles of Hamilton and Maupertuis, by O. Hölder.

June 20.—Attempted demonstration of orientation in the surface-conduction of electricity; on the continuous transition of an electrical property through the boundary-layer between solid and fluid bodies; on the conduction of electrified air; an experiment on magnetic currents, each by Ferdinand Braun.

July 4.—A contribution to the theory of complex magnitudes consisting of n primary units, by David Hilbert.

July 18.—Fluorescence and the kinetic theory, by W. Voigt.—On the change in the mode of vibration of light in passing through a dispersing or absorbing medium, by W. Voigt.

LYDEKKER'S GEOGRAPHICAL HISTORY OF MAMMALS.

A Geographical History of Mammals. By R. Lydekker, B.A., F.R.S., V.P.G.S., &c. Cambridge Geographical Series. Pp. xii + 400. (Cambridge: University Press, 1896.)

THERE can be no doubt about Mr. Lydekker's qualifications to enter on the field of geographical distribution. The author of the excellent treatise on mammals in the "Royal Natural History," after serving an apprenticeship on the Indian Geological Survey, has arranged and catalogued the splendid series of remains of extinct mammals in the British Museum. Alone of European palæontologists, he has likewise visited the rich collections recently amassed in the museums of Buenos Ayres and La Plata. He has thus the advantage, not possessed by any previous writer on the subject, of a more intimate acquaintance with the past history of mammals than perhaps any other living naturalist has been able to accumulate, and on the present occasion has made good use of it.

In the main outlines of his scheme of geographical regions, as propounded in the introductory chapter of the present work, Mr. Lydekker follows generally the well-known arrangement of Sclater and Wallace; but, as we shall presently show, deviates from their views in several important particulars. As to the correctness of the primary division of the earth's surface into "Notogæa," "Neogæa," and "Arctogæa," all authorities, we believe, whose opinions are worthy of consideration, are now nearly in accord. This arrangement was first proposed by Mr. Sclater in 1858, in one of the "Manchester Science Lectures," though other titles were then given to the two last-named divisions. In 1890, Dr. Blanford adopted the same primary areas with slight alterations in the names. The "anonymous writer" in *Natural Science*, who, in 1893, assigned the names "Notogæa," "Neogæa," and "Arctogæa" to these three divisions, we take to have been Mr. Sclater himself, or some one inspired by him. At any rate, these are the terms adopted by Mr. W. L. Sclater in his articles on the "Geography of Mammals," lately published in the *Geographical Journal*; and we agree with Mr. Lydekker in regarding them as the simplest and best-selected names yet proposed. But, having proceeded thus far, we have only arrived at the front of our difficulties.

"Arctogæa" embracing the whole land-surface of the world except Australia (*Notogæa*), and South and Central America (*Neogæa*), requires subdivision. Messrs. Sclater and Wallace have proposed to effect this in the most simple and natural way, by making four "regions" out of "Arctogæa"—namely, the Ethiopian, Oriental, Palæarctic and Nearctic, and thus to recognise six primary zoological regions. They admit, of course, that these six regions are not of exactly equal value. But in such a matter, as in all other classifications, convenience should be consulted to a certain extent, and the "six regions" are very convenient, being readily defined and easily recognisable, and are much more in accordance with facts than any other regions that have yet been suggested. Mr. Wallace has set all this fully forth in an address to the Cambridge Philosophical Society, which was published in this journal in April 1894.[1] We regret to observe that Mr. Lydekker scoffs at this excellent and well-reasoned article, and speaks of it as an attempt to "bolster up" a lost cause. Yet he continually refers to Mr. Wallace's writings throughout his work, and acknowledges his eminence as an authority on geographical distribution.

Mr. Lydekker summarises his objections to the "six regions" of Sclater and Wallace as follows:—

"It has the serious drawback that it gives no greater rank to Australasia and South America than to the other divisions; whilst the remarkable difference between the faunas of Africa and Madagascar is overlooked. Further, the northern parts of America are widely separated from those of Europe and Asia, to which they are faunistically allied."

Mr. Lydekker proposes the following modified scheme to meet the defects thus specified.

I. Notogæic realm	(1) Australian region.
	(2) Polynesian region.
	(3) Hawaian region.
	(4) Austro-Malayan region.
II. Neogæic realm	Neotropical region.
III. Arctogæic realm	(1) Malagasy region.
	(2) Ethiopian region.
	(3) Oriental region.
	(4) Holarctic region.
	(5) Sonoran region.

We venture to assert that these suggested modifications only lead Mr. Lydekker into further difficulties.

In the first place, realm is only region "writ short," and is hardly sufficiently distinct to be used in a different sense. Why not say simply "Notogæa," "Neogæa," and "Arctogæa"—three orthographically constructed compounds, of which the meaning is patent to all acquainted with the subject? Again, the so-called "Polynesian region" is a mere appendage of the Australian region. As Mr. Lydekker well says, it is "characterised by the general absence of non-flying mammals." But the birds—the next important group—are mostly Australian in character, though a few genera are autochthonous. The Moas (*Dinornithidæ*) which, until lately, played such an important *rôle* in it, are certainly as nearly related to the Cassowaries as to any other group. Lories (a specially characteristic Australian type) are scattered over it. In fact, Polynesia can only be properly placed as one of the sub-regions of the Australian region.

Much the same may be said of Mr. Lydekker's "Hawaian region." The only mammal of the Sandwich Islands is a bat. The land-birds are certainly very peculiar, and mostly restricted to the group. It is, as yet, not ascertained to what outside forms they are most nearly related; it is quite certain, however, they have nothing to do with America. But to rank the Hawaian Islands as constituting a division equal in value to the Ethiopian region is simply impossible. The alleged inequality of Sclater and Wallace's six regions is a trifle compared with this feat of Mr. Lydekker. The best place for the so-called "Hawaian region," so far as our present knowledge goes, is within the boundaries of the Australian.

[1] See "What are Zoological Regions?" (NATURE, vol. xlix. p. 611).

Again, the "Austro-Malayan region" of Mr. Lydekker is merely a border-land between the Australian and Oriental regions, and has no sort of claim to the rank here assigned to it. It has few, if any, indigenous types of mammals, and cannot for a moment be put on a par, as it is in Mr. Lydekker's scheme, with the Ethiopian region, which has numerous families, both of mammals and birds, restricted to its area. Mr. Lydekker's "Austro-Malayan region," except Celebes—which is certainly a difficult subject—may be safely annexed to the Australian region. Celebes has been also referred there by Mr. Wallace, but on the whole we opine that it would be better placed as a distinct sub-region of the Oriental region.

We now come to Mr. Lydekker's "Arctogæic realm," or "Arctogæa," as we prefer to call it. This is divided by Mr. Lydekker into five regions, as shown above. As regards the separation of Madagascar and its islands from the Ethiopian region, under the name of the "Malagasy region," there is much to be said in its favour, and we do not deny that our author has some good grounds to go upon. It is obvious that the mammal fauna of Madagascar, as well shown by Mr. Lydekker (see p. 215 of his work), is one of the most extraordinary on the world's surface—not only for what it has, but still more, perhaps, for what it has not. We can, therefore, offer no serious objection to Dr. Blanford's proposal (accepted by Mr. Lydekker) to raise the rank of Madagascar from that of a sub-region (as it has been treated by Messrs. Sclater and Wallace) to that of a full-blown region.

Mr. Lydekker's Ethiopian and Oriental regions remain much the same as Mr. Wallace's; but as regards the next two—the Holarctic and the Sonoran, there is a wide difference. Mr. Lydekker, misled by Dr. Merriam and other American writers, who take a narrow view of the subject, proposes to annex the northern part of America to the northern part of the Old World, calling it altogether Holarctic; while the more southern part of North America, down to the boundaries of the Neotropical region, is denominated "Sonoran." To assent to this proceeding, however, would only involve us in further difficulties. Most of the "Sonoran" mammals penetrate far into the north, outside its supposed limits. On examining the list of the Sonoran types (p. 379) and that of the "Western Division of the Holarctic region" (p. 344), we shall find them meagre indeed, and quite insufficient to support a distinction between two regions. The polar area may, in fact, be safely regarded as border-land between the Palæarctic and Nearctic regions. It must be recollected that Northern America was, in comparatively recent days, covered by the polar ice-sheet even much more extensive than that of Northern Europe. This destroyed nearly all animal life, and drove most of the remainder into Mr. Lydekker's "Sonoran region." On the disappearance of the ice-sheet the northern land was naturally repeopled from the adjacent part of Asia across Behring's Straits, as well as from the Sonoran region. Hence, no doubt, came such characteristic Palæarctic forms as the sheep, the bison, the mountain-goat, and the stag into North America. Of these, however, all but the mountain-goat have penetrated into the Sonoran region, and we have some doubts whether *Haploceros* is not likewise to be met with within its supposed boundaries.

Another serious objection to the "Holarctic region" is that, as regards birds at least, by adopting it we shall mix up some of the most characteristic forms of the New World in the same primary division as those of the Old World. Take, for example, the humming-birds—a most eminently typical group of the New World. Humming-birds range all over Canada in the summer, and on the west of the continent pass up to Alaska. Following Mr. Lydekker's scheme, we should have to place the Trochilidæ in the "Holarctic list." The same would be the case with the Mniotiltine warblers (*Mniotiltidæ*), the greenlets (*Vireonidæ*), the hang-nests (*Icteridæ*), and other forms which are absolutely restricted to America, and utterly foreign to the Old World (*Palæogean*) avifauna.

On the whole, therefore, we cannot doubt that Mr. Lydekker would have been more prudent to stick to the old-fashioned "six regions." Even had he not quite agreed to them, he might have sheltered himself under Mr. Wallace's authority, and safely followed his leadership.

In his intimate acquaintance with fossil mammals, Mr. Lydekker had, as we have already stated, a great advantage over his fellow-workers in the same field, and one of which he has not failed to make good use in some of his arguments. This branch of the subject is certainly much more completely discussed in the "Geographical History of Mammals" than in any other work of the same character, and we are duly grateful to the author for the many novel facts he has thus set before us. At the same time it should be recollected that, while we are pretty well acquainted with the present mammal-fauna of the earth and the facts of its distribution, we know comparatively little about the past. The "imperfection of the geological record" should be always in our minds when arguments are used taken from the little that is yet known of the ranges of extinct mammals, our notions of which may in many cases come to be seriously modified by discoveries yet to be made.

On the whole, however, we must allow that Mr. Lydekker's volume forms a valuable contribution to the "Cambridge Geographical Series," and that the general editor has done wisely in securing such a well-written essay on this branch of his subject from a palæontological point of view. Although we notice a few typographical errors, the volume is well printed, and excellently illustrated by numerous process-blocks introduced into the text, and by a chart of the zoological regions. Altogether it contains a large mass of information reduced into a small compass, and will meet, we are sure, with generous appreciation from all students of distribution.

THE RATIONAL STUDY OF PLANT-DISTRIBUTION.

Lehrbuch der Ökologischen Pflanzengeographie eine einführung in die kenntniss der Pflanzenvereine. Von Dr. Eugen Warming. Deutsche Ausgabe von Dr. E. Knoblauch. (Berlin: Gebrüder Borntraeger, 1896.)

AN account of the principles underlying the facts of the geographical distribution of plants has long been a desideratum. Although various persons have written on the subject, they have not, for the most part,

approached it from the point of view which, thanks largely to the often decried "laboratory system," we are enabled to do at the present time. In fact, until botanists had given up restricting their attention to species, and to the grosser external characters of plants, it was not possible for them to apprehend how intimately the welfare, and consequently the distribution, of the organism and of the species is bound up with minute and often apparently trivial details of structure. It is true that the general characters of what we may term the *Habitus* of groups of plants had been more or less clearly defined. Humboldt and Grisebach had already distinguished numerous dominant types, and had indicated the general nature of their relationships.

But what we want to find out is the causal *nexus* which exists between the plant, and the locality or conditions in which it lives. It is this, the biological, aspect of the question which is the important one for to-day. We are deeply conscious that life is a struggle between conflicting organisms more or less adapted to the conditions of life to which they are exposed. We know, too, that in this struggle, no factor is without its due weight in determining the final result. But we cannot hope to unravel the tangle of reasons which may account for the presence of this type here and its absence there, nor can we appreciate the nice adjustment between the individual constituents which compose the type, until we are in a position to investigate the inter-relations existing between the adaptation and the environment to which it responds. Before this could be, it was first necessary to obtain an insight, not only into the minute details of anatomy, but also into their connection with the functions discharged by the organism as a whole. Only then can we appreciate the true meaning of the peculiarities presented by members of such characteristic floras as alpines, epiphytes, mangrove swamps, and the like.

It is not that the problems of distribution have hitherto attracted but little interest—far from it—but that before they could be successfully grappled with, a laboratory training formed an indispensable preliminary. But it *is* only a preliminary. It is all very well to study collections of plants, whether in the form of pickled material, or herbarium specimens, or even as living beings in hothouses. It is only by travelling, and seeing the things as they actually grow under natural conditions, that one is in a position to estimate the importance of this or that structure, and its relation to the welfare or existence of the species. It may not be necessary to travel far in order to make some progress in this study. Our own country affords abundant opportunity to those who know how to use their eyes; still, there can be no question but that it is in tropical regions that the *purposefulness* of structural modifications most forcibly obtrudes itself on the mind of the observer.

The questions involved are most fascinating, and they are most intricate. Hence it is the more important that we should address our inquiries in an orderly manner if we are to successfully analyse and classify the numerous factors concerned. To indicate how this may be done is one of the objects of Prof. Warming's book, and he may fairly claim to have largely succeeded in his efforts.

He discusses, in the first place, the general effect of physical conditions on plant-life; and his remarks are always interesting, even where we do not quite agree with the conclusions to which he arrives. He then gives a short classification of the different characteristic groups of plants, which he assembles in four different divisions—the Hydrophytes, Xerophytes, Halophytes and Mesophytes, the last including what we may term normal vegetation. The key-note to his treatment of these four divisions is given in the ideal which he keeps before him, that of ascertaining the manner in which each type and each species places itself in harmony with its surroundings by means of morphological, anatomical, and physiological differentiation and adaptation. The book is essentially one of classification of these adaptations, and of the varied environments inhabited by plants, and it is one which ought to be read not only by botanists, but by all who care for the general questions concerning the distribution of living forms in water and on land.

J. B. F.

OUR BOOK SHELF.

Rivers and Canals. The Flow, Control, and Improvement of Rivers, and the Design, Construction and Development of Canals, both for Navigation and Irrigation; with Statistics of the Traffic on Inland Waterways. By Leveson Francis Vernon-Harcourt, M.A. In 2 vols. Vol. i., Rivers; vol. ii., Canals. 651 pp. and index; with 13 plates of illustrations. (Oxford: Clarendon Press, 1896.)

THE first edition of Mr. Vernon Harcourt's book on rivers and canals was published in 1882, and has been regarded as one of the standard books on the subjects of which it treats. The present edition is not merely a revise of the former one, but has been almost entirely re-written, and the subjects rearranged and brought up to date. The wide experience which the author has had, from being frequently called upon professionally to investigate and report on matters relating to rivers and harbours, and the active interest he has taken in the various navigation congresses which have been held in this and other countries during the last few years, fully entitle him to write with authority on the theory of river engineering, and the principles to be observed in carrying out works of improvement. The theoretical part of the book is supported by descriptions and illustrations of the chief works which have been carried out for the control and improvement of rivers, and the construction of canals. The book is written in a style that is thoroughly readable, and is not encumbered with detailed facts and information which, although of great value to an experienced engineer, are not required by a student or reader who wishes to become acquainted with general principles. On the whole, as would naturally be expected, the views expressed by the author are sound, and such as have received general acceptance by the most experienced engineers of this and other countries. There are, however, some matters dealt with on which engineering "doctors differ," and in these cases Mr. Vernon Harcourt would, perhaps, have added to the value of his book if he had given a little more credit to the views of other engineers who have devoted their attention to the same subject. The illustrations are very clear and effective, and add considerably in elucidating the descriptions in the text. In fact, both the author and the publisher deserve the thanks of the engineering profession for bringing up-to-date a work bearing on the management of our harbours and rivers, on the efficiency of which the prosperity of the navigation and commercial interests of this country so largely depend.

Elementary Practical Chemistry and Qualitative Analysis. By Frank Clowes, D.Sc. Lond., and J. Bernard Coleman, A.R.C.Sc. Pp. xvi + 224. (London: J. and A. Churchill, 1896.)

THIS book, which is founded on Prof. Clowes' larger "Practical Chemistry and Qualitative Analysis" is intended for the use of general students and of technical students in schools and colleges who are desirous of acquiring a general elementary knowledge of chemistry, and who propose to acquire this knowledge in the only true way, viz. by themselves performing experiments in a laboratory. For such students the book furnishes an admirable guide. The first eighty pages contain excellent instructions as to the preparation and use of apparatus, the methods of carrying out ordinary chemical operations, and the modes of demonstrating the properties of common gases and liquids. The remainder of the book is occupied with a course of qualitative analysis, which treats first, at considerable length, of the reactions for metals and for acid-radicles, and then of the actual analysis of simple and complex substances. There is, further, an appendix of useful tables and a good index.

The hand of the experienced and careful teacher is manifest throughout. The importance attached to cleanliness, neatness, and system in the rules given for working; the directions for the verification of the statements made, and for the keeping of the student's notebook; the precautions indicated as necessary for success in certain experiments, the careful attention to detail, and the emphasis given just where it is needed, show that the authors have knowledge not only of chemistry, but also of the "general and technical student," who, if he will observe the instructions, and work fairly through the book, cannot fail to acquire a real knowledge of his subject.

For boys and girls at school, we ourselves should recommend a course on somewhat different lines, starting, for instance, with air rather than with oxygen, following generally a historical sequence, taking the various chemical operations not *en bloc*, but as required in the course, and relegating qualitative analysis to a comparatively subordinate place. But taking things as they are, and accepting as a fact the existing requirements of various public examining bodies, this little work should prove widely useful as a carefully-arranged, clear, and accurate text-book.

Entomological Notes for the Young Collector. By William A. Morley. Pp. viii + 129. (London: Elliot Stock, 1896.)

THIS is a little book of the most popular kind, written with the intention of rendering the collecting of butterflies and moths easy to the youngest of beginners. It is illustrated by eight pages of figures representing apparatus, setting, &c., and the text is divided into twelve chapters, corresponding to the months of the year, each including a lesson on apparatus, collecting, rearing, &c., and a list of some of the principal *Lepidoptera* which appear in each month. The book may be useful to those for whom it is intended; and we congratulate the author on his good judgment in advising his readers to learn the Latin names, and to forget the English. Here and there a little revision would be useful; thus Entomology is defined as "that branch of natural history which bears special reference to four-winged insects known as butterflies and moths" (no other insects being even mentioned in the book); Cambridgeshire is the only locality given for *Papilio machaon* and *Vanessa antiopa*; *Lycæna artaxerxes* is said to be "generally distributed in England"; of *L. corydon*, we read "On chalk cliffs, common"; and moths which come to sugar are said, as a rule, not to come to light.

W. F. K.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

IT is dangerous for a mere mortal to take part in the strife of the gods, or for "gyrating"[1] mathematicians to join battle with biologists. But as the enthusiasm of Prof. Weldon for his subject has so largely perturbed my normal gyrations, that I have devoted many months to the statistical theory of evolution, perhaps I may be permitted a word or two on the subject of the present controversy.

To demonstrate that natural selection, whether secular or periodic, is actually taking place in any species, and to measure its amount, is in the present state of our knowledge one of the grandest pieces of work that could be done. It would achieve for the Darwinian theory what Hertz achieved for the Maxwellian theory of light. At present no one has gone further in the direction of this demonstration than Prof. Weldon, and I am inclined to think with Mr. Thiselton-Dyer—and I take it in opposition to Prof. Lankester—that such a demonstration can only be achieved by the statistical method. If, however, we are to obtain a really solid result of that method, then the mathematical theory, and the logic used, must both be beyond suspicion. Now in any demonstration of the existence of natural selection two points must be borne in mind:

(*a*) A selective death-rate must be actually demonstrated. This is a problem for fine statistical theory.

(*b*) The correlation between organ and death-rate must be shown in itself to be not fortuitous. The character must have been selected because it is useful. This I take to be Prof. Lankester's point.

I propose to say a few words as to both (*a*) and (*b*).

It appears to me that both Prof. Lankester and Mr. Thiselton-Dyer allow that a selective death-rate has been established in the report on *Carcinas mænas* of 1894–5. This view I take to be entirely erroneous, and I so expressed myself to Prof. Weldon and several members of the Committee before the *Report* was published. What Prof. Weldon demonstrates is this—*that if crabs chanced to grow in a particular manner*, then there would be a relation between death-rate and the size of a certain frontal ratio. What is quite certain is that at the time the *Report* was published, nobody knew how crabs grew; and I very much doubt whether Prof. Weldon, after his laborious two years' study of the growth of crabs, would now uphold the hypotheses he then adopted, *e.g.*:

(i.) That size could be taken as a safe measure of age.

(ii.) That young crabs of the same frontal ratio do not "scatter" as they grow older.

(iii.) That the amount of growth of crabs of any given frontal ratio is entirely independent of that ratio.

Yet if these—to me very improbable—hypotheses be not accepted, the supposed demonstration of a selective death-rate in *Carcinas mænas* falls completely to the ground. The very hypothetical character of the conclusions of the *Report* of 1894–5, appears by his letter of August 26 to be now very fully recognised by Prof. Weldon himself. I am not, however, sure that it has been generally recognised. When the law of growth of crabs has been accurately ascertained, then I am convinced that it will require much more complex analysis than that of the *Report* to ascertain whether a selective death-rate does or does not exist. I should not have said so much on this first point did I not believe that next to blindly rejecting natural selection, the most dangerous course open to biologists is to accept a proof of its existence which is sure one day to be demonstrated as fallacious by one of the many opponents of Darwinism.

On the second point, surely Prof. Lankester is entirely in the right? It is not sufficient to show that there is a correlation between a certain frontal ratio and death-rate in order to assert that the frontal ratio is a cause of death-rate. Very probably it may be, but the demonstration is not logically complete, or at any rate a definition of cause has been adopted which does not appear

[1] The term is due to Prof. Lankester, who thus described us—I think it was to Mr. Thiselton-Dyer—in the early days of the Teaching University movement.

of much utility to science. If the height of the barometer be correlated with the frequency of explosions in mines, it would not appear utile to describe the barometer as a "cause" of the explosion. Or, to take another case, which is purely hypothetical, but which will, I think, illustrate Prof. Ray Lankester's point. There is, we will suppose, a purely random distribution of supernumerary teats in cows. But in my particular herd the two best milkers possess supernumerary teats (although there is no correlation between such teats and good milkers in general). I keep the calves of these two cows because they are good milkers, and by reason of this selection supernumerary teats become more and more common in my herd. At last I begin to preserve calves with supernumerary teats, really because this is a test of their descent from the good milkers, practically because I find them in themselves good milkers. Now, because I am a careful breeder, my cows may get a reputation at sales all over the country, and a correlation between supernumerary teats and good milkers may come to be generally recognised. This happens not because supernumerary teats are a cause of good milkers, but owing in the original instance to a *random* association of this variation with a utile variation. Thus, a primarily random association with a favourable variation may by the principle of heredity quite easily lead to a correlation which it would be of no profit to consider causal. If two characters be not correlated, and one be favourable to survival, then any selection of the favourable character, which hits a group of individuals having more than the average of the second character—and this may easily arise if we breed from comparatively few individuals—will by the principle of heredity lead to a *fortuitous* correlation. I do not assert that this is the case in the frontal ratio of crabs, but it seems to me that a link is really missing in the chain of demonstration. All causality is of course correlation, but the converse, which Prof. Weldon seems to hold and Prof. Lankester to controvert, is surely a dangerous doctrine?

KARL PEARSON.

September 10.

Specific Characters among the Mutillidæ.

THE discussion in your columns as to the utility of specific characters leads me to offer a few remarks on the Mutillidæ, an interesting family of Hymenoptera. In the arid region of the United States, this family is very numerously represented, and its members may be seen running about in warm weather, especially frequenting sandy places, roads and pathways. It is not at first apparent why the species should be so numerous, living under what seem to be identical or almost identical conditions; in 1893 (*Trans. Amer. Ent. Soc.*, xx. 343), I wrote: "It is difficult to account for the origin of so many species under conditions which can hardly at any time have been very diverse." But the region in question is inhabited by very many species of bees, the modifications of which have relation to a varied flora, as I have illustrated by particular instances elsewhere (*Proc. Ac. Nat. Sci. Phila.*, 1896, pp. 33–41). The various Mutillidæ are parasitic in the nests of these bees, and consequently do not live under identical conditions; we have a varied flora with its varied insect-visitors, and these with varied parasites, the whole series of phenomena intimately connected, though at first sight it would seem impossible to see any connection between the flowers and the mutillids, however indirect.

It must be a long time before the actual host-relations of all the mutillids are known, but I have a species now under observation, which may serve as an example. The bee *Diadasia diminuta* lives in colonies, burrowing perpendicular tunnels in the beaten pathway, which are produced somewhat above the level of the ground by means of fragile cylinders of sandy particles, designed to keep the tunnels from being filled with sand. The little *Sphærophthalma heterochroa* is the parasite of this bee, and the females may be seen in numbers running about between the burrows, now and then looking into them or entering. At once we see the utility of one of the specific characters of *S. heterochroa*—its small size. The larger species could not enter the small burrows of the bee.

The females of *S. heterochroa* are splendid little insects, ornamented with scarlet, black, and whitish. Like the females of all Mutillidæ, they are wingless. The much more active winged males, which are not so elegantly ornamented as the females, may be seen bustling about, looking for the latter. In the Mutillidæ, the females are very varied in colour, markings and structure; while the males are much more uniform. Thus, Cameron says ("Biol. Cent. Amer. Hymenoptera," p. 259): "This general resemblance of the males not only makes their specific determination a work of difficulty, but it adds greatly to the task of assigning them to their respective partners of the opposite sex." If the bright and varied colours and markings were due to activity or a "katabolic tendency," it is in the winged males that they ought to be found; not, as is actually the case, in the wingless females. But on the principle of utility there may be an explanation. The males have to look for their respective females, and I believe the ornamentation of the latter assists their recognition.

There is a whole series of Mutillidæ which are very plainly coloured, from tawny through various shades to black, never with any scarlet, or conspicuous markings. These (*Photopsis* and *Brachycistis*) are all nocturnal, without any exception, and come to lights in the evening. But the systematists who have described many of these insects, were totally unaware of this circumstance until I pointed it out recently!

The moral of all this is, that to understand the real meaning of specific characters we must study the species in nature. We are hardly more likely to understand natural phenomena from the examination of dead animals alone, than a Hottentot would be to understand the apparatus of telegraphy. And eventually, I believe even the pure systematist will have to base his work on biological observation. It has been fondly hoped all along that absolute criteria of specific distinction would be found in the insects themselves, without reference to their habits; and the searchers for such "hall-marks," driven from point to point, have at length taken refuge in the male genitalia. But only a few days ago I received the following in a letter from M. Ernest André, the distinguished French student of Hymenoptera, and particularly Mutillidæ.

"Comme je l'ai dit, je crois qu'on attache aujourd'hui une trop grande importance aux caractères tirés de l'appareil génital mâle. Ces organes sont très variables, difficiles à apprécier, et ne concordent pas toujours avec les autres caractères morphologiques."

The Khmer of Kamboja.

IN NATURE, June 11, p. 135, I see a short notice of the work being done in Australia by Prof. R. Semon, of Jena, and that he classes the "Khmer and Chams of Kamboja" as "primitive Dravido-Australians." I hope that some of your anthropological experts will, as soon as possible, correct this serious mistake.

Mr. A. H. Keane, in NATURE, January 6, 1881, p. 222, calls these people "Caucasian"; but I presume they are now (1896) known to be what Captain C. J. F. S. Forbes classed them, *i.e.* Mon-Anam, in his "Languages of Further India."

J. R. Logan, in his "Ethnology of the Indo-Pacific Islands," published at Singapur and Pinang, in the *Journal* of the Indian Archipelago (1847–63), rightly classes them as Mon-Anam, giving their linguistic peculiarities and alliances, pronouns, &c., and numerals up to ten, those from one to five being identical with our Kol, Sontal, Munda, Ho (the most western relatives of the Mon-Anam alliance), and quite different to the Dravidian numerals.

The now civilised Kambojans admit that the "Khmer dom" are the older and purer stock, whence they are descended, and that they were *hill savages*, which carries out what we know so far of these early *pre*-Burmo-Tibetan races from the Asam side.

Both in physique and languages, the Dravido-Austral aboriginal of India (south of Himalaya) and the Mon-Anam group are very distinct; the former are seen purest in the Andamani and Negrito, in whom there is an entire absence of Tibetan elements.

But the Mon-Anam (which includes the Khmer) were formed, as a race, by the mixture, or fusion, of (Sifan) Tibetans with the Dravidians, lying south of Himalaya from Nipal to East Asam. At one time this "Mon-Anam" race appears to have covered all Northern and Eastern Bengal, the whole of Asam,

and the Ultra-Indian peninsula from Asam to Singapore, and even to have extended to the Nicobars, Sumatra, Borneo, and beyond. In India, on the west and south-west, the Tibetan element dies out, and gives place (gradually) to the purer Dravidian; and here we have the darker Kol alliance, Munda, Santali, &c., say, roughly, two-thirds Dravidian and one-third Tibetan. Further east we have the relics of the Mon in the Bodo, Koch, Mech, of the Delta, and the Garo-Kasia of the eastern hills, the latter more Tibetanised by later influx of Tibetans *viâ* Bhutan, in physique and language.

Then we have a vast gap filled in by later "Tibeto-Burman" races, and come to the "Mon" of Pegu, who show the influence of the Tibeto-Burman inroads, though retaining still considerable "Kasia" affinities. The Kambojans, again, are another fragment of the "Mon," having specific affinities with Manipuri and Naga. Anamese, again, is distinguished by its strong Manipuri, Barak, and Kol affinities, and showing Chinese influence, through contiguity becoming more monosyllabic.

Logan, who was an expert in these matters, tells us that "the Mon-Anam pronouns and numerals are partly Tibetan and partly Dravidian—chiefly the latter—but most of the substantial roots are similar to Tibetan, and the forms more archaic than the current Tibeto-Burman." "The difference between Dravido-Australian and the Mon-Anam formation is so great, that it may be safely connected with the equally striking difference of race, and ascribed to a long-continued and total ethnic separation during its earlier history. The Simang and Andamani are the purest remnants of a pre-Himalaic race in Ultra-India, and it is probable that similar Dravido-Australian tribes [lived there] before the Mon-Anam entered the region."

But one of the best proofs that the "Khmer" are not Dravido-Australian is, that the Australian races all have numerals on the binary basis 1 and 2. Three is 2 + 1 or 1 + 2. Four is 2 + 2. Five is 2 + 2 + 1. This was formerly the basis of the Dravidian system, long before the Mon-Anam (Khmer, &c.) arose as a race.

The Australians, in fact, whose languages are known to be "more nearly allied to the South Indian than to any other in the world," left India (probably *viâ* Malaya) when the Dravidian numerals were in their earliest binary stage, and before the quinary and denary stage was developed (anywhere).

As Logan says, "the quinary and denary systems, with the Dravidian mode of forming 8 and 9, indicate affinities belonging to much later periods. The civilisation which originated them, was unknown to Dravido-Australian at the time when the early Asonasian migrations took place."

That the Mon-Anam race, much later on, passed south and east from India, and extended even over the Archipelago and Pacific, is becoming yearly more obvious, not only through study of physique and customs, but the number of roots, pronouns, and vocables having a *Himalaic* basis. But from their site of origin, in Bengal, as a (locally varied) admixture of Tibetan and Dravidian, the racial development and tribal drift may have been exceedingly slow, like the drift we see now among the much later Tibeto-Burman, Lushai Kuki, &c., taking probably many centuries in crossing from the Delta, across the Barak, Manipuri, and Naga Ranges, and *viâ* Asam. That they at one time covered the entire Ultra-Indian peninsula, is obvious from the position of the fragments of the race, due to the intrusion of the Tibeto-Burmans, but that they extended to the east of the Upper Irawadi is doubtful.

The Cham, Charay, Stieng, Xong, Samré, and Kuy are the less known, more barbarous, and purer branches of the Mon-Anam living in the Mekong highlands. S. E. PEAL.

Sibsagar, Asam, August 11.

Dr. Siemens' Smokeless Open Grate.

DR. C. WILLIAM SIEMENS described fully in NATURE (November 11, 1880, vol. xxiii. p. 25) a smokeless open gas and coke or gas and anthracite grate for living rooms, costing about one halfpenny per hour in fuel. Will any users of this grate, who may have an extended experience of it, relate their views, and state any lessons its use may have taught them?

During an extensive hunt for a smokeless open cheap grate, Dr. Siemens' grate is the most satisfactory I have yet found.

FRED. WM. FOSTER.

Neckinger Mills, Bermondsey, September 9.

THE LIVERPOOL MEETING OF THE BRITISH ASSOCIATION.

IV.

LIVERPOOL, *September* 14.

WE are now on the eve of the meeting. St. George's Hall opens to-day as the British Association reception-room; and although the attendance on the first day will be chiefly Liverpool people securing their seats for the evening addresses in the Philharmonic Hall, still a few visitors from other parts of the country and from abroad have already arrived, and many more are expected to-morrow. We are told that more associates' and ladies' tickets have now been taken than at any previous meeting on the corresponding day. These local ticket-holders, along with the members from elsewhere who have intimated their intention of being present, amounted on Saturday to about 2500, so there is every prospect of a large gathering.

The last meeting, for the present, of the Executive Committee was held on Friday, and the local secretaries then reported upon the final arrangements for the meeting. The Town Hall will probably prove too small for the number of members who will attend the first soirée, so the Lord Mayor (the Earl of Derby) has obtained permission from the Committee of the Exchange News-room, across the Exchange "flags," to utilise that magnificent hall, in addition to the Town Hall, for his entertainment. A covered way will connect the front of the Exchange News-room with one of the windows of the Town Hall.

At the second soirée, to be held in the Walker Art Gallery, Free Library, and Museum, the accommodation is ample, so provision is being made for short lectures, lantern demonstrations, and various exhibitions in the galleries and rooms.

Nothing has been changed in the other Sectional arrangements and fixtures already announced, but some additional information has come in regard to the probable work of Sections F, I and K.

In the Section of Economics and Statistics, the proceedings on Thursday will be opened at 11 a.m. by the Presidential Address, which will deal with economic teaching and political action. The treatment of this subject derives much additional importance from the almost unique position in the political world occupied by the President (the Right Hon. L. Courtney). In due consideration that the meeting takes place this year in a large and busy commercial centre like Liverpool, several sittings will be devoted to the consideration of matters of directly practical, as well as theoretic interest. On one day (Friday), three papers will be given by Messrs. Cannan, W. H. Smith, and Blunden on various points relating to the incidence of local rates and the municipal control of finance. On another day (Monday), future dealings in produce will form the subject of discussion. Papers dealing with these will be contributed by Mr. H. R. Rathbone, Mr. Charles Stewart, and Mr. E. Helm, of Manchester. On Tuesday, currency questions will occupy the attention of the Section, when it is hoped that a paper will be read in defence of the gold standard by Mr. William Fowler. One or two papers from the bimetallic side are promised. Other papers will deal with the effects of trade amalgamations, systems of economic education, standard of value and money, commercial crises, cotton prices, remedies for agricultural distress, metric system, and other important subjects. It is hoped that there will be included among these a consideration of some aspects of charitable and philanthropic trading, by Mr. C. S. Loch.

In the "Section of Physiology, including Psychophysics and Experimental Pathology," in addition to the Presidential Address and the discussions already

announced, some of the more important communications will be as follows:—"Further researches on the phonograph," and "Method of transmitting wave-forms from phonograms to paper," by Prof. McKendrick; "Method of distinguishing between organic and inorganic compounds of iron in the tissues," by Prof. Macallum (Toronto); "The glycoside constitution of proteid matter," by Dr. Pavy; "Photometry and Purkinje's phenomenon," by Prof. Haycroft; "Bacteria and daily food," by Dr. Kanthack; "The physiological effects of peptone when injected into the circulation," by Prof. Thompson; "The influence of glycerine on the growth of bacteria," by Dr. Markton Copeman; and other papers by Dr. Dupuy, Prof. Gotch, Dr. Mann, Prof. Boyce, &c.

In the Botanical Section, in addition to what we have already announced, there will be two discussions on subjects which have for some time past been prominently before the botanical world. On Friday, Mr. Francis Darwin will introduce a discussion on the movements of water in plants; others will be followed by a demonstration by Prof. Vines of a new method for the experimental investigation of some phenomena connected with the transpiration current. On Tuesday the second discussion will be opened by Prof. Farmer. This will treat of problems connected with the vegetable cell, but it is hoped that with the co-operation of zoologists the subject will be discussed from a general biological point of view.

An important contribution by Miss Sargant will be made after the discussion, in which some recent researches on nuclear division will be described.

On Monday afternoon, as already announced, a lecture will be delivered by Mr. Thiselton-Dyer, on the geographical distribution of plants. The subject will be treated in such a way as to appeal not only to specialists, but to the wider circle of those who possess a general interest in botanical science.

The papers to be communicated to this Section may be summarised as follows. Prof. Magnus (of Berlin), Mr. Ellis, and Mr. Vaughan Jennings have promised communications on the life-history of various Fungi. Dr. Mann is expected to make a communication on work carried out by Miss Huit on the physiology of the tentacles of *Drosera;* and from Dr. Morris (of Kew), there will be a contribution on some remarkable pathological effects produced by a West Indian weed, *Leucæna glauca*. On Monday, Prof. Chodat (of Geneva) will give an account of conclusions arrived at as the result of his important researches on Algæ, relating to such problems as the origin of sexuality, and the relationship of Algæ to the higher plants.

Prof. Bower and Mr. Lang (of Glasgow) will deal with investigations on Vascular Cryptogams, and from the latter author may be expected an exceedingly important contribution which has a direct bearing on the question of alternation of generations treated of in the President's opening address. Palæobotanical papers are to be read by the President and Mr. Seward on Palæozoic and Mesozoic plants. It is hoped that Prof. Trail (of Aberdeen) may give an account of his extensive researches on the variation in flower structure of the *Polygonaceæ;* and Mr. Scott-Elliot will probably read a paper on the effect of habitat on the habits of plants. Results of anatomical and physiological interest will be communicated by Mr. Keeble and Mr. Gwynne-Vaughan.

Although the hope that Nansen might have attended this meeting will not be realised, we shall have Sir Martin Conway fresh from Spitzbergen, and an account will be given by Mr. Montefiore Bryce of the experiences in Franz Josef Land of the Jackson-Harmsworth Expedition.

Amongst recent additions to the list of foreigners and Americans expected are:—Prof. Fokkar (Gröningen), Prof. Johannes Walther (Jena), Dr. Montelius (Stockholm), Prof. Keeler (Pennsylvania), Dr. Stolpe (Stockholm), Prof. Zacharias (Hamburg), Dr. Herrschen (Upsala), Dr. Johann Hjort (Christiania), M. Theodore Nica (Bucharest), Prof. Bohnslav Brauner (Prague), Prof. Nasini (Padua), Prof. Yves Delage (Paris), Prof. J. Berg (Stockholm), Prof. R. Chodat (Geneva), Prof. Kohlrausch (Berlin), M. J. Violle (Paris). Other distinguished guests who will attend were mentioned in a former article.

Before this appears in print the presidential and other opening addresses will have been given, and the character of the meeting will have declared itself; but as far as present indications afford a clue, we may expect an unusually large gathering, and a number of important discussions in the Sections. How far these forecasts and expectations have been realised will appear in our final article.

W. A. HERDMAN.

INAUGURAL ADDRESS BY SIR JOSEPH LISTER, BART., D.C.L., LL.D., P.R.S., PRESIDENT.

MY Lord Mayor, my Lords, Ladies, and Gentlemen, I have first to express my deep sense of gratitude for the great honour conferred upon me by my election to the high office which I occupy to-day. It came upon me as a great surprise. The engrossing claims of surgery have prevented me for many years from attending the meetings of the Association, which excludes from her Sections medicine in all its branches. This severance of the art of healing from the work of the Association was right and indeed inevitable. Not that medicine has little in common with science. The surgeon never performs an operation without the aid of anatomy and physiology; and in what is often the most difficult part of his duty, the selection of the right course to follow, he, like the physician, is guided by pathology, the science of the nature of disease, which, though very difficult from the complexity of its subject matter, has made during the last half-century astonishing progress; so that the practice of medicine in every department is becoming more and more based on science as distinguished from empiricism. I propose on the present occasion to bring before you some illustrations of the interdependence of science and the healing art; and the first that I will take is perhaps the most astonishing of all results of purely physical inquiry—the discovery of the Röntgen rays, so called after the man who first clearly revealed them to the world. Mysterious as they still are, there is one of their properties which we can all appreciate—their power of passing through substances opaque to ordinary light. There seems to be no relation whatever between transparency in the common sense of the term and penetrability to these emanations. The glasses of a pair of spectacles may arrest them while their wooden and leathern case allows them to pass almost unchecked. Yet they produce, whether directly or indirectly, the same effects as light upon a photographic plate. As a general rule the denser any object is the greater obstacle does it oppose to the rays. Hence, as bone is denser than flesh, if the hand or other part of the body is placed above the sensitive film enclosed in a case of wood or other light material at a suitable distance from the source of the rays, while they pass with the utmost facility through the uncovered parts of the lid of the box and powerfully affect the plate beneath, they are arrested to a large extent by the bones, so that the plate is little acted upon in the parts opposite to them, while the portions corresponding to the muscles and other soft parts are influenced in an intermediate degree. Thus a picture is obtained in which the bones stand out in sharp relief among the flesh, and anything abnormal in their shape or position is clearly displayed.

I need hardly point out what important aid this must give to the surgeon. As an instance, I may mention a case which occurred in the practice of Mr. Howard Marsh. He was called to see a severe injury of the elbow, in which the swelling was so great as to make it impossible for him by ordinary means of examination to decide whether he had to deal with a fracture or a dislocation. If it were the latter, a cure would be effected by the exercise of violence which would be not only useless but most injurious if a bone was broken. By the aid of the Röntgen rays a photograph was taken in which the bone of the upper arm was clearly seen displaced forwards on those of the forearm. The diagnosis being thus established, Mr. Marsh proceeded to reduce the dislocation; and his success was proved by another photograph which showed the bones in their natural relative position.

The common metals, such as lead, iron, and copper, being

still denser than the osseous structures, these rays can show a bullet embedded in a bone or a needle lodged about a joint. At the last conversazione of the Royal Society a picture produced by the new photography displayed with perfect distinctness through the bony framework of the chest a halfpenny low down in a boy's gullet. It had been there for six months, causing uneasiness at the pit of the stomach during swallowing; but whether the coin really remained impacted, or if so, what was its position, was entirely uncertain till the Röntgen rays revealed it. Dr. Macintyre of Glasgow, who was the photographer, informs me that when the presence of the halfpenny had been thus demonstrated, the surgeon in charge of the case made an attempt to extract it, and although this was not successful in its immediate object, it had the effect of dislodging the coin; for a subsequent photograph by Dr. Macintyre not only showed that it had disappeared from the gullet, but also, thanks to the wonderful penetrating power which the rays had acquired in his hands, proved that it had not lodged further down in the alimentary passage. The boy has since completely recovered.

The Röntgen rays cause certain chemical compounds to fluoresce, and emit a faint light plainly visible in the dark; and if they are made to fall upon a translucent screen impregnated with such a salt, it becomes beautifully illuminated. If a part of the human body is interposed between the screen and the source of the rays, the bones and other structures are thrown in shadow upon it, and thus a diagnosis can be made without the delay involved in taking a photograph. It was in fact in this way that Dr. Macintyre first detected the coin in the boy's gullet. Mr. Herbert Jackson, of King's College, London, early distinguished himself in this branch of the subject. There is no reason to suppose that the limits of the capabilities of the rays in this way have yet been reached. By virtue of the greater density of the heart than the adjacent lungs with their contained air, the form and dimensions of that organ in the living body may be displayed on the fluorescent screen, and even its movements have been lately seen by several different observers.

Such important applications of the new rays to medical practice have strongly attracted the interest of the public to them, and I venture to think that they have even served to stimulate the investigations of physicists. The eminent Professor of Physics in the University of College of this city (Prof. Lodge) was one of the first to make such practical applications, and I was able to show to the Royal Society at a very early period a photograph, which he had the kindness to send me, of a bullet embedded in the hand. His interest in the medical aspect of the subject remains unabated, and at the same time he has been one of the most distinguished investigators of its purely physical side.

There is another way in which the Röntgen rays connect themselves with physiology, and may possibly influence medicine. It is found that if the skin is long exposed to their action it becomes very much irritated, affected with a sort of aggravated sun-burning. This suggests the idea that the transmission of the rays through the human body may be not altogether a matter of indifference to internal organs, but may, by long-continued action, produce, according to the condition of the part concerned, injurious irritation or salutary stimulation.

This is the jubilee of Anæsthesia in surgery. That priceless blessing to mankind came from America. It had, indeed, been foreshadowed in the first year of this century by Sir Humphry Davy, who, having found a toothache from which he was suffering relieved as he inhaled laughing gas (nitrous oxide), threw out the suggestion that it might perhaps be used for preventing pain in surgical operations. But it was not till, on September 30, 1846, Dr. W. T. G. Morton, of Boston, after a series of experiments upon himself and the lower animals, extracted a tooth painlessly from a patient whom he had caused to inhale the vapour of sulphuric ether, that the idea was fully realised. He soon afterwards publicly exhibited his method at the Massachusetts General Hospital, and after that event the great discovery spread rapidly over the civilised world. I witnessed the first operation in England under ether. It was performed by Robert Liston in University College Hospital, and it was a complete success. Soon afterwards I saw the same great surgeon amputate the thigh as painlessly, with less complicated anæsthetic apparatus, by aid of another agent, chloroform, which was being powerfully advocated as a substitute for ether by Dr. (afterwards Sir James Y.) Simpson, who also had the great merit of showing that confinements could be conducted painlessly, yet safely, under its influence. These two agents still hold the field as general anæsthetics for protracted operations, although the gas originally suggested by Davy, in consequence of its rapid action and other advantages, has taken their place in short operations, such as tooth extraction. In the birthplace of anæsthesia ether has always maintained its ground; but in Europe it was to a large extent displaced by chloroform till recently, when many have returned to ether, under the idea that, though less convenient, it is safer. For my own part, I believe that chloroform, if carefully administered on right principles, is, on the average, the safer agent of the two.

The discovery of anæsthesia inaugurated a new era in surgery. Not only was the pain of operations abolished, but the serious and sometimes mortal shock which they occasioned to the system was averted, while the patient was saved the terrible ordeal of preparing to endure them. At the same time the field of surgery became widely extended, since many procedures in themselves desirable, but before impossible from the protracted agony they would occasion, became matters of routine practice. Nor have I by any means exhausted the list of the benefits conferred by this discovery.

Anæsthesia in surgery has been from first to last a gift of science. Nitrous oxide, sulphuric ether, and chloroform are all artificial products of chemistry, their employment as anæsthetics was the result of scientific investigation, and their administration, far from being, like the giving of a dose of medicine, a matter of rule of thumb, imperatively demands the vigilant exercise of physiological and pathological knowledge.

While rendering such signal service to surgery, anæsthetics have thrown light upon biology generally. It has been found that they exert their soporific influence not only vertebrata, but upon animals so remote in structure from man as bees and other insects. Even the functions of vegetables are suspended by their agency. They thus afford strong confirmation of the great generalisation that living matter is of the same essential nature wherever it is met with on this planet, whether in the animal or vegetable kingdom. Anæsthetics have also, in ways to which I need not here refer, powerfully promoted the progress of physiology and pathology.

My next illustration may be taken from the work of Pasteur on fermentation. The prevailing opinion regarding this class of phenomena when they first engaged his attention was that they were occasioned primarily by the oxygen of the air acting upon unstable animal or vegetable products, which, breaking up under its influence, communicated disturbance to other organic materials in their vicinity, and thus led to their decomposition. Cagniard-Latour had indeed shown several years before that yeast consists essentially of the cells of a microscopic fungus which grows as the sweetwort ferments; and he had attributed the breaking up of the sugar into alcohol and carbonic acid to the growth of the micro-organism. In Germany Schwann, who independently discovered the yeast plant, had published very striking experiments in support of analogous ideas regarding the putrefaction of meat. Such views had also found other advocates, but they had become utterly discredited, largely through the great authority of Liebig, who bitterly opposed them.

Pasteur, having been appointed as a young man Dean of the Faculty of Sciences in the University of Lille, a town where the products of alcoholic fermentation were staple articles of manufacture, determined to study that process thoroughly; and as a result he became firmly convinced of the correctness of Cagniard-Latour's views regarding it. In the case of other fermentations, however, nothing fairly comparable to the formation of yeast had till then been observed. This was now done by Pasteur for that fermentation in which sugar is resolved into lactic acid. This lactic fermentation was at that time brought about by adding some animal substance, such as fibrin, to a solution of sugar, together with chalk that should combine with the acid as it was formed. Pasteur saw, what had never before been noticed, that a fine grey deposit was formed, differing little in appearance from the decomposing fibrin, but steadily increasing as the fermentation proceeded. Struck by the analogy presented by the increasing deposit to the growth of yeast in sweetwort, he examined it with the microscope, and found it to consist of minute particles of uniform size. Pasteur was not a biologist, but although these particles were of extreme minuteness in comparison with the constituents of the yeast plant, he felt convinced that they were of an analogous nature, the cells of a tiny microscopic fungus. This he regarded as the essential ferment, the fibrin or other so-called ferment serving, as he believed, merely

the purpose of supplying to the growing plant certain chemical ingredients not contained in the sugar but essential to its nutrition. And the correctness of this view he confirmed in a very striking manner, by doing away with the fibrin or other animal material altogether, and substituting for it mineral salts containing the requisite chemical elements. A trace of the grey deposit being applied to a solution of sugar containing these salts in addition to the chalk, a brisker lactic fermentation ensued than could be procured in the ordinary way.

I have referred to this research in some detail because it illustrates Pasteur's acuteness as an observer and his ingenuity in experiment, as well as his almost intuitive perception of truth.

A series of other beautiful investigations followed, clearly proving that all true fermentations, including putrefaction, are caused by the growth of micro-organisms.

It was natural that Pasteur should desire to know how the microbes which he showed to be the essential causes of the various fermentations took their origin. It was at that period a prevalent notion, even among many eminent naturalists, that such humble and minute beings originated *de novo* in decomposing organic substances; the doctrine of spontaneous generation, which had been chased successively from various positions which it once occupied among creatures visible to the naked eye, having taken its last refuge where the objects of study were of such minuteness that their habits and history were correspondingly difficult to trace. Here again Pasteur at once saw, as if by instinct, on which side the truth lay; and perceiving its immense importance, he threw himself with ardour into its demonstration. I may describe briefly one class of experiments which he performed with this object. He charged a series of narrow-necked glass flasks with a decoction of yeast, a liquid peculiarly liable to alteration on exposure to the air. Having boiled the liquid in each flask, to kill any living germs it might contain, he sealed its neck with a blow-pipe during ebullition; after which, the flask being allowed to cool, the steam within it condensed, leaving a vacuum above the liquid. If, then, the neck of the flask were broken in any locality, the air at that particular place would rush in to fill the vacuum, carrying with it any living microbes that might be floating in it. The neck of the flask having been again sealed, any germs so introduced would in due time manifest their presence by developing in the clear liquid. When any of such a series of flasks were opened and re-sealed in an inhabited room, or under the trees of a forest, multitudes of minute living forms made their appearance in them; but if this was done in a cellar long unused, where the suspended organisms, like other dust, might be expected to have all fallen to the ground, the decoction remained perfectly clear and unaltered. The oxygen and other gaseous constituents of the atmosphere were thus shown to be of themselves incapable of inducing any organic development in yeast-water.

Such is a sample of the many well-devised experiments by which he carried to most minds the conviction that, as he expressed it, *la génération spontanée est une chimère*, and that the humblest and minutest living organisms can only originate by parentage from beings like themselves.

Pasteur pointed out the enormous importance of these humble organisms in the economy of nature. It is by their agency that the dead bodies of plants and animals are resolved into simpler compounds fitted for assimilation by new living forms. Without their aid the world would be, as Pasteur expresses it, *encombré de cadavres*. They are essential not only to our well-being, but to our very existence. Similar microbes must have discharged the same necessary function of removing refuse and providing food for successive generations of plants and animals during the past periods of the world's history; and it is interesting to think that organisms as simple as can well be conceived to have existed when life first appeared upon our globe have, in all probability, propagated the same lowly but most useful offspring during the ages of geological time.

Pasteur's labours on fermentation have had a very important influence upon surgery. I have been often asked to speak on my share in this matter before a public audience; but I have hitherto refused to do so, partly because the details are so entirely technical, but chiefly because I have felt an invincible repugnance to what might seem to savour of self-advertisement. The latter objection now no longer exists, since advancing years have indicated that it is right for me to leave to younger men the practice of my dearly loved profession. And it will perhaps be expected that, if I can make myself intelligible, I should say something upon the subject on the present occasion.

Nothing was formerly more striking in surgical experience than the difference in the behaviour of injuries according to whether the skin was implicated or not. Thus, if the bones of the leg were broken and the skin remained intact, the surgeon applied the necessary apparatus without any other anxiety than that of maintaining a good position of the fragments, although the internal injury to bones and soft parts might be very severe. If, on the other hand, a wound of the skin was present communicating with the broken bones, although the damage might be in other respects comparatively slight, the compound fracture, as it was termed, was one of the most dangerous accidents that could happen. Mr. Syme, who was, I believe, the safest surgeon of his time, once told me that he was inclined to think that it would be, on the whole, better if all compound fractures of the leg were subjected to amputation, without any attempt to save the limb. What was the cause of this astonishing difference? It was clearly in some way due to the exposure of the injured parts to the external world. One obvious effect of such exposure was indicated by the odour of the discharge, which showed that the blood in the wound had undergone putrefactive change by which the bland nutrient liquid had been converted into highly irritating and poisonous substances. I have seen a man with compound fracture of the leg die within two days of the accident, as plainly poisoned by the products of putrefaction as if he had taken a fatal dose of some potent toxic drug.

An external wound of the soft parts might be healed in one of two ways. If its surfaces were clean cut and could be brought into accurate apposition, it might unite rapidly and painlessly "by the first intention." This, however, was exceptional. Too often the surgeon's efforts to obtain primary union were frustrated: the wound inflamed and the retentive stitches had to be removed, allowing it to gape; and then, as if it had been left open from the first, healing had to be effected in the other way which it is necessary for me briefly to describe. An exposed raw surface became covered in the first instance with a layer of clotted blood or certain of its constituents, which invariably putrefied; and the irritation of the sensitive tissues by the putrid products appeared to me to account sufficiently for the inflammation which always occurred in and around an open wound during the three or four days which elapsed before what were termed "granulations" had been produced. These constituted a coarsely granular coating of very imperfect or embryonic structure, destitute of sensory nerves and prone to throw off matter or pus, rather than absorb, as freshly divided tissues do, the products of putrefaction. The granulations thus formed a beautiful living plaster, which protected the sensitive parts beneath from irritation, and the system generally from poisoning and consequent febrile disturbance. The granulations had other useful properties of which I may mention their tendency to shrink as they grew, thus gradually reducing the dimensions of the sore. Meanwhile another cause of its diminution was in operation. The cells of the epidermis or scarf-skin of the cutaneous margins were perpetually producing a crop of young cells of similar nature, which gradually spread over the granulations till they covered them entirely, and a complete cicatrix or scar was the result. Such was the other mode of healing, that by granulation and cicatrisation; a process which, when it proceeded unchecked to its completion, commanded our profound admiration. It was, however, essentially tedious compared with primary union, while, as we have seen, it was always preceded by more or less inflammation and fever, sometimes very serious in their effects. It was also liable to unforeseen interruptions. The sore might become larger instead of smaller, cicatrisation giving place to ulceration in one of its various forms, or even to the frightful destruction of tissue which, from the circumstance that it was most frequently met with in hospitals, was termed hospital gangrene. Other serious and often fatal complications might arise, which the surgeon could only regard as untoward accidents and over which he had no efficient control.

It will be readily understood from the above description that the inflammation which so often frustrated the surgeon's endeavours after primary union was in my opinion essentially due to decomposition of blood within the wound.

These and many other considerations had long impressed me with the greatness of the evil of putrefaction in surgery. I had done my best to mitigate it by scrupulous ordinary cleanliness and the use of various deodorant lotions. But to prevent it

altogether appeared hopeless while we believed with Liebig that its primary cause was the atmospheric oxygen which, in accordance with the researches of Graham, could not fail to be perpetually diffused through the porous dressings which were used to absorb the blood discharged from the wound. But when Pasteur had shown that putrefaction was a fermentation caused by the growth of microbes, and that these could not arise *de novo* in the decomposable substance, the problem assumed a more hopeful aspect. If the wound could be treated with some substance which, without doing too serious mischief to the human tissues, would kill the microbes already contained in it and prevent the future access of others in the living state, putrefaction might be prevented, however freely the air with its oxygen might enter. I had heard of carbolic acid as having a remarkable deodorising effect upon sewage, and having obtained from my colleague Dr. Anderson, Professor of Chemistry in the University of Glasgow, a sample which he had of this product, then little more than a chemical curiosity in Scotland, I determined to try it in compound fractures. Applying it undiluted to the wound, with an arrangement for its occasional renewal, I had the joy of seeing these formidable injuries follow the same safe and tranquil course as simple fractures, in which the skin remains unbroken.

At the same time we had the intense interest of observing in open wounds what had previously been hidden from human view, the manner in which subcutaneous injuries are repaired. Of special interest was the process by which portions of tissue killed by the violence of the accident were disposed of, as contrasted with what had till then been invariably witnessed. Dead parts had been always seen to be gradually separated from the living by an inflammatory process and thrown off as sloughs. But when protected by the antiseptic dressing from becoming putrid and therefore irritating, a structure deprived of its life caused no disturbance in its vicinity; and, on the contrary, being of a nutritious nature, it served as pabulum for the growing elements of the neighbouring living structures, and these became in due time entirely substituted for it. Even dead bone was seen to be thus replaced by living osseous tissue.

This suggested the idea of using threads of dead animal tissue for tying blood-vessels; and this was realised by means of catgut, which is made from the intestine of the sheep. If deprived of living microbes, and otherwise properly prepared, catgut answers its purpose completely; the knot holding securely, while the ligature around the vessel becomes gradually absorbed and replaced by a ring of living tissue. The threads, instead of being left long as before, could now be cut short, and the tedious process of separation of the ligature, with its attendant serious danger of bleeding, was avoided.

Undiluted carbolic acid is a powerful caustic; and although it might be employed in compound fracture, where some loss of tissue was of little moment in comparison with the tremendous danger to be averted, it was altogether unsuitable for wounds made by the surgeon. It soon appeared, however, that the acid would answer the purpose aimed at, though used in diluted forms devoid of caustic action, and therefore applicable to operative surgery. According to our then existing knowledge, two essential points had to be aimed at: to conduct the operation so that on its completion the wound should contain no living microbes, and to apply a dressing capable of preventing the access of other living organisms till the time should have arrived for changing it.

Carbolic acid lent itself well to both these objects. Our experience with this agent brought out what was, I believe, a new principle in pharmacology—namely, that the energy of action of any substance upon the human tissues depends not only upon the proportion in which it is contained in the material used as a vehicle for its administration, but also upon the degree of tenacity with which it is held by its solvent. Water dissolves carbolic acid sparingly and holds it extremely lightly, leaving it free to act energetically on other things for which it has greater affinity, while various organic substances absorb it greedily and hold it tenaciously. Hence its watery solution seemed admirably suited for a detergent lotion to be used during the operation for destroying any microbes that might fall upon the wound, and for purifying the surrounding skin and also the surgeon's hands and instruments. For the last-named purpose it had the further advantage that it did not act on steel.

For an external dressing the watery solution was not adapted, as it soon lost the acid it contained, and was irritating while it lasted. For this purpose some organic substances were found to answer well. Large proportions of the acid could be blended with them in so bland a form as to be unirritating; and such mixtures, while perpetually giving off enough of the volatile salt to prevent organic development in the discharges that flowed past them, served as a reliable store of the antiseptic for days together.

The appliances which I first used for carrying out the antiseptic principle were both rude and needlessly complicated. The years that have since passed have witnessed great improvements in both respects, of the various materials which have been employed by myself and others, and their modes of application, I need say nothing except to express my belief, as a matter of long experience, that carbolic acid, by virtue of its powerful affinity for the epidermis and oily matters associated with it, and also its great penetrating power, is still the best agent at our disposal for purifying the skin around the wound. But I must say a few words regarding a most important simplification of our procedure. Pasteur, as we have seen, had shown that the air of every inhabited room teems with microbes; and for a long time I employed various more or less elaborate precautions against the living atmospheric dust, not doubting that, as all wounds except the few which healed completely by the first intention underwent putrefactive fermentation, the blood must be a peculiarly favourable soil for the growth of putrefactive microbes. But I afterwards learnt that such was by no means the case. I had performed many experiments in confirmation of Pasteur's germ theory, not indeed in order to satisfy myself of its truth, but in the hope of convincing others. I had observed that uncontaminated milk, which would remain unaltered for an indefinite time if protected from dust, was made to teem with microbes of different kinds by a very brief exposure to the atmosphere, and that the same effect was produced by the addition of a drop of ordinary water. But when I came to experiment with blood drawn with antiseptic precautions into sterilised vessels, I saw to my surprise that it might remain free from microbes in spite of similar access of air or treatment with water. I even found that if very putrid blood was largely diluted with sterilised water, so as to diffuse its microbes widely and wash them of their acrid products, a drop of such dilution added to pure blood might leave it unchanged for days at the temperature of the body, although a trace of the septic liquid undiluted caused intense putrefaction within twenty-four hours. Hence I was led to conclude that it was the grosser forms of septic mischief, rather than microbes in the attenuated condition in which they existed in the atmosphere, that we had to dread in surgical practice. And at the London Medical Congress in 1881, I hinted, when describing the experiments I have alluded to, that it might turn out possible to disregard altogether the atmospheric dust. But greatly as I should have rejoiced at such a simplification of our procedure, if justifiable, I did not then venture to test it in practice. I knew that with the safeguards which we then employed I could ensure the safety of my patients, and I did not dare to imperil it by relaxing them. There is one golden rule for all experiments upon our fellow-men. Let the thing tried be that which, according to our best judgment, is the most likely to promote the welfare of the patient. In other words, Do as you would be done by.

Nine years later, however, at the Berlin Congress in 1890, I was able to bring forward what was, I believe, absolute demonstration of the harmlessness of the atmospheric dust in surgical operations. This conclusion has been justified by subsequent experience: the irritation of the wound by antiseptic irrigation and washing may therefore now be avoided, and nature left quite undisturbed to carry out her best methods of repair, while the surgeon may conduct his operations as simply as in former days, provided always that, deeply impressed with the tremendous importance of his object, and inspiring the same conviction in all his assistants, he vigilantly maintains from first to last, with a care that, once learnt, becomes instinctive, but for the want of which nothing else can compensate, the use of the simple means which will suffice to exclude from the wound the coarser forms of septic impurity.

Even our earlier and ruder methods of carrying out the antiseptic principle soon produced a wonderful change in my surgical wards in the Glasgow Royal Infirmary, which, from being some of the most unhealthy in the kingdom, became, as I believe I may say without exaggeration, the healthiest in the world; while other wards, separated from mine only by a passage a few feet broad, where former modes of treatment were for awhile continued, retained their former insalubrity. This result, I need hardly remark, was not in any degree due to special skill on my

part, but simply to the strenuous endeavour to carry out strictly what seemed to me a principle of supreme importance.

Equally striking changes were afterwards witnessed in other institutions. Of these I may give one example. In the great Allgemeines Krankenhaus of Munich, hospital gangrene had become more and more rife from year to year, till at length the frightful condition was reached that 80 per cent. of all wounds became affected by it. It is only just to the memory of Prof. von Nussbaum, then the head of that establishment, to say that he had done his utmost to check this frightful scourge; and that the evil was not caused by anything peculiar in his management was shown by the fact that in a private hospital under his care there was no unusual unhealthiness. The larger institution seemed to have become hopelessly infected, and the city authorities were contemplating its demolition and reconstruction. Under these circumstances, Prof. von Nussbaum despatched his chief assistant, Dr. Lindpaintner, to Edinburgh, where I at that time occupied the chair of Clinical Surgery, to learn the details of the antiseptic system as we then practised it. He remained until he had entirely mastered them, and after his return all the cases were on a certain day dressed on our plan. From that day forward not a single case of hospital gangrene occurred in the Krankenhaus. The fearful disease pyæmia likewise disappeared, and erysipelas soon followed its example.

But it was by no means only in removing the unhealthiness of hospitals that the antiseptic system showed its benefits. Inflammation being suppressed, with attendant pain, fever, and wasting discharge, the sufferings of the patient were, of course, immensely lessened; rapid primary union being now the rule, convalescence was correspondingly curtailed; while as regards safety and the essential nature of the mode of repair, it became a matter of indifference whether the wound had clean-cut surfaces which could be closely approximated, or whether the injury inflicted had been such as to cause destruction of tissue. And operations which had been regarded from time immemorial as unjustifiable were adopted with complete safety.

It pleases me to think that there is an ever-increasing number of practitioners throughout the world to whom this will not appear the language of exaggeration. There are cases in which, from the situation of the part concerned or other unusual circumstances, it is impossible to carry out the antiseptic system completely. These, however, are quite exceptional; and even in them much has been done to mitigate the evil which cannot be altogether avoided.

I ask your indulgence if I have seemed to dwell too long upon matters in which I have been personally concerned. I now gladly return to the labours of others.

The striking results of the application of the germ theory to surgery acted as a powerful stimulus to the investigation of the nature of the micro-organisms concerned; and it soon appeared that putrefaction was by no means the only evil of microbic origin to which wounds were liable. I had myself very early noticed that hospital gangrene was not necessarily attended by any unpleasant odour; and I afterwards made a similar observation regarding the matter formed in a remarkable epidemic of erysipelas in Edinburgh obviously of infective character. I had also seen a careless dressing followed by the occurrence of suppuration without putrefaction. And as these non-putrefactive disorders had the same self-propagating property as ferments, and were suppressed by the same antiseptic agencies which were used for combating the putrefactive microbes, I did not doubt that they were of an analogous origin; and I ventured to express the view that, just as the various fermentations had each its special microbe, so it might be with the various complications of wounds. This surmise was afterwards amply verified. Prof. Ogston, of Aberdeen, was an early worker in this field, and showed that in acute abscesses, that is to say those which run a rapid course, the matter, although often quite free from unpleasant odour, invariably contains micro-organisms belonging to the group which, from the spherical form of their elements, are termed micrococci; and these he classed as streptococci or staphylococci, according as they were arranged in chains or disposed in irregular clusters like bunches of grapes. The German pathologist, Fehleisen, followed with a beautiful research, by which he clearly proved that erysipelas is caused by a streptococcus. A host of earnest workers in different countries have cultivated the new science of Bacteriology, and, while opening up a wide fresh domain of Biology, have demonstrated in so many cases the causal relation between special micro-organisms and special diseases, not only in wounds but in the system generally, as to afford ample confirmation of the induction which had been made by Pasteur that all infective disorders are of microbic origin.

Not that we can look forward with anything like confidence to being able ever to see the *materies morbi* of every disease of this nature. One of the latest of such discoveries has been that by Pfeiffer of Berlin of the bacillus of influenza, perhaps the most minute of all micro-organisms ever yet detected. The bacillus of anthrax, the cause of a plague common among cattle in some parts of Europe, and often communicated to sorters of foreign wool in this country, is a giant as compared with this tiny being; and supposing the microbe of any infectious fever to be as much smaller than the influenza bacillus as this is less than that of anthrax, a by no means unlikely hypothesis, it is probable that it would never be visible to man. The improvements of the microscope, based on the principle established by my father in the earlier part of the century, have apparently nearly reached the limits of what is possible. But that such parasites are really the causes of all this great class of diseases can no longer be doubted.

The first rational step towards the prevention or cure of disease is to know its cause; and it is impossible to overestimate the practical value of researches such as those to which I am now referring. Among their many achievements is what may be fairly regarded as the most important discovery ever made in pathology, because it revealed the true nature of the disease which causes more sickness and death in the human race than any other. It was made by Robert Koch, who greatly distinguished himself when a practitioner in an obscure town in Germany, by the remarkable combination of experimental acuteness and skill, chemical and optical knowledge and successful micro-photography which he brought to bear upon the illustration of infective diseases of wounds in the lower animals; in recognition of which service the enlightened Prussian Government at once appointed him to an official position of great importance in Berlin. There he conducted various important researches; and at the London congress in 1881 he showed to us for the first time the bacillus of tubercle. Wonderful light was thrown by this discovery upon a great group of diseases which had before been rather guessed than known to be of an allied nature; a precision and efficacy never before possible was introduced into their surgical treatment, while the physician became guided by new and sure light as regards their diagnosis and prevention.

At that same London congress Koch demonstrated to us his "plate culture" of bacteria, which was so important, that I must devote a few words to its description. With a view to the successful study of the habits and effects of any particular microbe outside the living body, it is essential that it should be present unmixed in the medium in which it is cultivated. It can be readily understood how difficult it must have been to isolate any particular micro-organism when it existed mixed, as was often the case, with a multitude of other forms. In fact, the various ingenious attempts made to effect this object had often proved entire failures. Koch, however, by an ingenious procedure converted what had been before impossible into a matter of utmost facility. In the broth or other nutrient liquid which was to serve as food for the growing microbe he dissolved, by the aid of heat, just enough gelatine to ensure that, while it should become a solid mass when cold, it should remain fluid though reduced in temperature so much as to be incapable of killing living germs. To the medium thus partially cooled was added some liquid containing, among others, the microbe to be investigated; and the mixture was thoroughly shaken so as to diffuse the bacteria and separate them from each other. Some of the liquid was then poured out in a thin layer upon a glass plate and allowed to cool so as to assume the solid form. The various microbes, fixed in the gelatine and so prevented from intermingling, proceeded to develop each its special progeny, which in course of time showed itself as an opaque speck in the transparent film. Any one of such specks could now be removed and transferred to another vessel in which the microbe composing it grew in perfect isolation.

Pasteur was present at this demonstration, and expressed his sense of the great progress effected by the new method. It was soon introduced into his own institute and other laboratories throughout the world; and it has immensely facilitated bacteriological study.

One fruit of it in Koch's own hands was the discovery of the microbe of cholera in India, whither he went to study the disease. This organism was termed by Koch from its curved

form the "comma bacillus," and by the French the cholera vibrio. Great doubts were for a long time felt regarding this discovery. Several other kinds of bacteria were found of the same shape, some of them producing very similar appearances in culture media. But bacteriologists are now universally agreed that, although various other conditions are necessary to the production of an attack of cholera besides the mere presence of the vibrio, yet it is the essential *materies morbi*; and it is by the aid of the diagnosis which its presence in any case of true cholera enables the bacteriologist to make, that threatened invasions of this awful disease have of late years been so successfully repelled from our shores. If bacteriology had done nothing more for us than this, it might well have earned our gratitude.

I have next to invite your attention to some earlier work of Pasteur. There is a disease known in France under the name of *choléra des poules*, which often produced great havoc among the poultry yards of Paris. It had been observed that the blood of birds that had died of this disease was peopled by a multitude of minute bacteria, not very dissimilar in form and size to the microbe of the lactic ferment to which I have before referred. And Pasteur found that, if this bacterium was cultivated outside the body for a protracted period under certain conditions, it underwent a remarkable diminution of its virulence; so that, if inoculated into a healthy fowl, it no longer caused the death of the bird, as it would have done in its original condition, but produced a milder form of the disease which was not fatal. And this altered character of the microbe, caused by certain conditions, was found to persist in successive generations cultivated in the ordinary way. Thus was discovered the great fact of what Pasteur termed the *atténuation des virus*, which at once gave the clue to understanding what had before been quite mysterious, the difference in virulence of the same disease in different epidemics.

But he made the further very important observation that a bird which had gone through the mild form of the complaint, had acquired immunity against it in its most virulent condition. Pasteur afterwards succeeded in obtaining mitigated varieties of microbes for some other diseases; and he applied with great success the principle which he had discovered in fowl-cholera for protecting the larger domestic animals against the plague of anthrax. The preparations used for such preventive inoculations he termed "vaccins," in honour of our great countryman, Edward Jenner. For Pasteur at once saw the analogy between the immunity to fowl-cholera produced by its attenuated virus, and the protection afforded against small-pox by vaccination. And while pathologists still hesitated, he had no doubt of the correctness of Jenner's expression *variolæ vaccinæ*, or small-pox in the cow.

It is just a hundred years since Jenner made the crucial experiment of inoculating with small-pox a boy whom he had previously vaccinated, the result being, as he anticipated, that the boy was quite unaffected. It may be remarked that this was a perfectly legitimate experiment, involving no danger to the subject of it. Inoculation was at that time the established practice; and if vaccination should prove nugatory, the inoculation would be only what would have been otherwise called for; while it would be perfectly harmless if the hoped-for effect of vaccination had been produced.

We are a practical people, not much addicted to personal commemorations; although our nation did indeed celebrate with fitting splendour the jubilee of the reign of our beloved Queen; and at the invitation of Glasgow the scientific world has lately marked in a manner, though different, as imposing, the jubilee of the life-work of a sovereign in science (Lord Kelvin). But while we cannot be astonished that the centenary of Jenner's immortal discovery should have failed to receive general recognition in this country, it is melancholy to think that this year should, in his native county, have been distinguished by a terrible illustration of the results which would sooner or later inevitably follow the general neglect of his prescriptions.

I have no desire to speak severely of the Gloucester Guardians. They are not sanitary authorities, and had not the technical knowledge necessary to enable them to judge between the teachings of true science and the declamations of misguided, though well-meaning, enthusiasts. They did what they believed to be right; and when roused to a sense of the greatness of their mistake, they did their very best to repair it, so that their city is said to be now the best vaccinated in her Majesty's dominions. But, though by their praiseworthy exertions they succeeded in promptly checking the raging epidemic, they cannot recall the dead to life, or restore beauty to marred features, or sight to blinded eyes. Would that the entire country and our Legislature might take duly to heart this object-lesson!

How completely the medical profession were convinced of the efficacy of vaccination in the early part of this century, was strikingly illustrated by an account given by Prof. Crookshank, in his interesting history of this subject, of several eminent medical men in Edinburgh meeting to see the (to them) unprecedented fact of a vaccinated person having taken small-pox. It has, of course, since become well known that the milder form of the disease, as modified by passing through the cow, confers a less permanent protection than the original human disorder. This it was, of course, impossible for Jenner to foresee. It is, indeed, a question of degree, since a second attack of ordinary small-pox is occasionally known to occur; and vaccination, long after it has ceased to give perfect immunity, greatly modifies the character of the disorder, and diminishes its danger. And, happily, in re-vaccination after a certain number of years we have the means of making Jenner's work complete. I understand that the majority of the Commissioners, who have recently issued their report upon this subject, while recognising the value and importance of re-vaccination, are so impressed with the difficulties that would attend making it compulsory by legislation that they do not recommend that course; although it is advocated by two of their number who are of peculiarly high authority on such a question. I was lately told by a Berlin professor that no serious difficulty is experienced in carrying out the compulsory law that prevails in Germany. The masters of the schools are directed to ascertain in the case of every child attaining the age of twelve whether re-vaccination has been practised. If not, and the parents refuse to have it done, they are fined one mark. If this does not prove effectual, the fine is doubled; and if even the double penalty should not prove efficacious, a second doubling of it would follow; but, as my informant remarked, it is very seldom that it is called for. The result is that small-pox is a matter of extreme rarity in that country, while it is absolutely unknown in the huge German army, in consequence of the rule that every soldier is re-vaccinated on entering the service. Whatever view our Legislature may take on this question, one thing seems to me clear: that it will be the duty of Government to encourage by every available means the use of calf lymph, so as to exclude the possibility of the communication of any human disease to the child, and to institute such efficient inspection of vaccination institutes as shall ensure careful antiseptic arrangements, and so prevent contamination by extraneous microbes. If this were done, "conscientious objections" would cease to have any rational basis. At the same time, the administration of the regulations on vaccination should be transferred (as advised by the Commissioners) to competent sanitary authorities.

But to return to Pasteur. In 1880 he entered upon the study of that terrible but then most obscure disease, hydrophobia or rabies, which from its infective character he was sure must be of microbic origin, although no micro-organism could be detected in it. He early demonstrated the new pathological fact that the virus had its essential seat in the nervous system. This proved the key to his success in this subject. One result that flowed from it has been the cause of unspeakable consolation to many. The foolish practice is still too prevalent of killing the dog that has bitten any one, on the absurd notion that, if it were mad, its destruction would prevent the occurrence of hydrophobia in the person bitten. The idea of the bare possibility of the animal having been so affected causes an agony of suspense during the long weeks or months of possible incubation of the disease. Very serious nervous symptoms aping true hydrophobia have been known to result from the terror thus inspired. Pasteur showed that if a little of the brain or spinal cord of a dog that had been really mad was inoculated in an appropriate manner into a rabbit, it infallibly caused rabies in that animal in a few days. If, therefore, such an experiment was made with a negative result, the conclusion might be drawn with certainty that the dog had been healthy. It is perhaps right that I should say that the inoculation is painlessly done under an anæsthetic, and that in the rabbit rabies does not assume the violent form that it does in the dog, but produces gradual loss of power with little if any suffering.

This is the more satisfactory because rabbits in which the disease has been thus artificially induced are employed in carrying out what was Pasteur's greatest triumph, the preventive

treatment of hydrophobia in the human subject. We have seen that Pasteur discovered that microbes might under some circumstances undergo mitigation of their virulence. He afterwards found that under different conditions they might have it exalted, or, as he expressed it, there might be a *renforcement du virus*. Such proved to be the case with rabies in the rabbit; so that the spinal cords of animals which had died of it contained the poison in a highly intensified condition. But he also found that if such a highly virulent cord was suspended under strict antiseptic precautions in a dry atmosphere at a certain temperature, it gradually from day to day lost in potency, till in course of time it became absolutely inert. If now an emulsion of such a harmless cord was introduced under the skin of an animal, as in the subcutaneous administration of morphia, it might be followed without harm another day by a similar dose of a cord still rather poisonous; and so from day to day stronger and stronger injections might be used, the system becoming gradually accustomed to the poison, till a degree of virulence had been reached far exceeding that of the bite of a mad dog. When this had been attained, the animal proved incapable of taking the disease in the ordinary way; and more than that, if such treatment was adopted after an animal had already received the poison, provided that too long a time had not elapsed, the outbreak of the disease was prevented. It was only after great searching of heart that Pasteur, after consultation with some trusted medical friends, ventured upon trying this practice upon man. It has since been extensively adopted in various parts of the world with increasing success as the details of the method were improved. It is not of course the case that every one bitten by a really rabid animal takes the disease; but the percentage of those who do so, which was formerly large, has been reduced almost to zero by this treatment, if not too long delayed.

While the intensity of rabies in the rabbit is undoubtedly due to a peculiarly virulent form of the microbe concerned, we cannot suppose that the daily diminishing potency of the cord suspended in dry warm air is an instance of attenuation of virus, using the term "virus" as synonymous with the microbe concerned. In other words, we have no reason to believe that the special micro-organism of hydrophobia continues to develop in the dead cord and produce successively a milder and milder progeny, since rabies cannot be cultivated in the nervous system of a dead animal. We must rather conclude that there must be some chemical poison present which gradually loses its potency as time passes. And this leads me to refer to another most important branch of this large subject of bacteriology, that of the poisonous products of microbes.

It was shown several years ago by Roux and Yersin, working in the Institut Pasteur, that the crust or false membrane which forms upon the throats of patients affected with diphtheria contains bacteria which can be cultivated outside the body in a nutrient liquid, with the result that it acquires poisonous qualities of astonishing intensity, comparable to that of the secretion of the poison-glands of the most venomous serpents. And they also ascertained that the liquid retained this property after the microbes had been removed from it by filtration, which proved that the poison must be a chemical substance in solution, as distinguished from the living element which had produced it. These poisonous products of bacteria, or toxins as they have been termed, explain the deadly effects of some microbes, which it would otherwise be impossible to understand. Thus, in diphtheria itself the special bacillus which was shown by Löffler to be its cause, does not become propagated in the blood, like the microbe of chicken cholera, but remains confined to the surface on which it first appeared; but the toxin which it secretes is absorbed from that surface into the blood, and so poisons the system. Similar observations have been made with regard to the microbes of some other diseases, as, for example, the bacillus of tetanus or lockjaw. This remains localised in the wound, but forms a special toxin of extreme potency, which becomes absorbed and diffused through the body.

Wonderful as it seems, each poisonous microbe appears to form its own peculiar toxin. Koch's tuberculin was of this nature, a product of the growth of the tubercle bacillus in culture media. Here, again, great effects were produced by extremely minute quantities of the substance, but here a new peculiarity showed itself, viz. that patients affected with tubercular disease, in any of its varied forms, exhibited inflammation in the affected part and general fever after receiving under the skin an amount of the material which had no effect whatever upon healthy persons. I witnessed in Berlin some instances of these effects, which were simply astounding. Patients affected with a peculiar form of obstinate ulcer of the face showed, after a single injection of the tuberculin, violent inflammatory redness and swelling of the sore and surrounding skin; and, what was equally surprising, when this disturbance subsided the disease was found to have undergone great improvement. By repetitions of such procedures, ulcers which had previously been steadily advancing, in spite of ordinary treatment, became greatly reduced in size, and in some instances apparently cured. Such results led Koch to believe that he had obtained an effectual means of dealing with tnbercular disease in all its forms. Unhappily, the apparent cure proved to be only of transient duration, and the high hopes which had been inspired by Koch's great reputation was dashed. It is but fair to say that he was strongly urged to publish before he was himself disposed to do, and we cannot but regret that he yielded to the pressure put upon him.

But though Koch's sanguine anticipations were not realised, it would be a great mistake to suppose that his labours with tuberculin have been fruitless. Cattle are liable to tubercle, and, when affected with it, may become a very serious source of infection for human beings, more especially when the disease affects the udders of cows, and so contaminates the milk. By virtue of the close affinity that prevails between the lower animals and ourselves, in disease as well as in health, tuberculin produces fever in tubercular cows in doses which do not affect healthy beasts. Thus, by the subcutaneous use of a little of the fluid, tubercle latent in internal organs of an apparently healthy cow can be with certainty revealed, and the slaughter of the animal after this discovery protects man from infection.

It has been ascertained that glanders presents a precise analogy with tubercle as regards the effects of its toxic product. If the microbe which has been found to be the cause of this disease is cultivated in appropriate media, it produces a poison which has received the name of mallein, and the subcutaneous injection of a suitable dose of this fluid into a glandered horse causes striking febrile symptoms which do not occur in a healthy animal. Glanders, like tubercle, may exist in insidious latent forms which there was formerly no means of detecting, but which are at once disclosed by this means. If a glandered horse has been accidentally introduced into a large stable, this method of diagnosis surely tells if it has infected others. All receive a little mallein. Those which become affected with fever are slaughtered, and thus not only is the disease prevented from spreading to other horses, but the grooms are protected from a mortal disorder.

This valuable resource sprang from Koch's work on tuberculin, which has also indirectly done good in other ways. His distinguished pupil, Behring, has expressly attributed to those researches the inspiration of the work which led him and his since famous collaborateur, the Japanese Kitasato, to their surprising discovery of anti-toxic serum. They found that if an animal of a species liable to diphtheria or tetanus received a quantity of the respective toxin, so small as to be harmless, and afterwards, at suitable intervals, successively stronger and stronger doses, the creature, in course of time, acquired such a tolerance for the poison as to be able to receive with impunity a quantity very much greater than would at the outset have proved fatal. So far, we have nothing more than seems to correspond with the effects of the increasingly potent cord in Pasteur's treatment of rabies. But what was entirely new in their results was that, if blood was drawn from an animal which had acquired this high degree of artificial immunity, and some of the clear fluid or serum which exuded from it after it had clotted was introduced under the skin of another animal, this second animal acquired a strong, though more transient, immunity against the particular toxin concerned. The serum in some way counteracted the toxin or was antitoxic. But, more than that, if some of the antitoxic serum was applied to an animal after it had already received a poisonous dose of the toxin, it preserved the life of the creature, provided that too long a time had not elapsed after the poison was introduced. In other words, the antitoxin proved to be not only preventive but curative.

Similar results were afterwards obtained by Ehrlich, of Berlin, with some poisons not of bacterial origin, but derived from the vegetable kingdom; and quite recently the independent labours of Calmette of Lille and Fraser of Edinburgh have shown that antidotes of wonderful efficacy against the venom of serpents may be procured on the same principle. Calmette has obtained

antitoxin so powerful that a quantity of it only a 200,000th part of the weight of an animal will protect it perfectly against a dose of the secretion of the poison glands of the most venomous serpents known to exist, which without such protection would have proved fatal in four hours. For curative purposes larger quantities of the remedy are required, but cases have been already published by Calmette in which death appears to have been averted in the human subject by this treatment.

Behring's darling object was to discover means of curing tetanus and diphtheria in man. In tetanus the conditions are not favourable; because the specific bacilli lurk in the depths of the wound, and only declare their presence by symptoms caused by their toxin having been already in a greater or less amount diffused through the system; and in every case of this disease there must be a fear that the antidote may be applied too late to be useful. But in diphtheria the bacilli very early manifest their presence by the false membrane which they cause upon the throat, so that the antitoxin has a fair chance; and here we are justified in saying that Behring's object has been attained.

The problem, however, was by no means so simple as in the case of some mere chemical poison. However effectual the antitoxin might be against the toxin, if it left the bacilli intact, not only would repeated injections be required to maintain the transient immunity to the poison perpetually secreted by the microbes, but the bacilli might by their growth and extension cause obstruction of the respiratory passages.

Roux, however, whose name must always be mentioned with honour in relation to this subject, effectually disposed of this difficulty. He showed by experiments on animals that a diphtheritic false membrane, rapidly extending and accompanied by surrounding inflammation, was brought to a stand by the use of the antitoxin, and soon dropped off, leaving a healthy surface. Whatever be the explanation, the fact was thus established that the antitoxic serum, while it renders the toxin harmless, causes the microbe to languish and disappear.

No theoretical objection could now be urged against the treatment; and it has during the last two years been extensively tested in practice in various parts of the world, and it has gradually made its way more and more into the confidence of the profession. One important piece of evidence in its favour in this country is derived from the report of the six large hospitals under the management of the London Asylums Board. The medical officers of these hospitals at first naturally regarded the practice with scepticism; but as it appeared to be at least harmless, they gave it a trial; and during the year 1895 it was very generally employed upon the 2182 cases admitted; and they have all become convinced of its great value. In the nature of things, if the theory of the treatment is correct, the best results must be obtained when the patients are admitted at an early stage of the attack, before there has been time for much poisoning of the system; and accordingly we learn from the report that, comparing 1895 with 1894, during which latter year the ordinary treatment had been used, the percentage of mortality, in all the six hospitals combined, among the patients admitted on the first day of the disease, which in 1894 was 22·5, was only 4·6 in 1895; while for those admitted on the second day the numbers are 27 for 1894 and 14·8 for 1895. Thus for cases admitted on the first day the mortality was only one-fifth of what it was in the previous year, and for those entering on the second it was halved. Unfortunately, in the low parts of London, which furnish most of these patients, the parents too often delay sending in the children till much later: so that on the average no less than 67·5 per cent. were admitted on the fourth day of the disease or later. Hence the aggregate statistics of all cases are not nearly so striking. Nevertheless, taking it altogether, the mortality in 1895 was less than had ever before been experienced in those hospitals. I should add that there was no reason to think that the disease was of a milder type than usual in 1895; and no change whatever was made in the treatment except as regards the antitoxic injections.

There is one piece of evidence recorded in the report which, though it is not concerned with high numbers, is well worthy of notice. It relates to a special institution to which convalescents from scarlet fever are sent from all the six hospitals. Such patients occasionally contract diphtheria, and when they do so the added disease has generally proved extremely fatal. In the five years preceding the introduction of the treatment with antitoxin the mortality from this cause had never been less than 50 per cent., and averaged on the whole 61·9 per cent. During 1895, under antitoxin, the deaths among the 119 patients of this class were only 7·5 per cent., or one-eighth of what had been previously experienced. This very striking result seems to be naturally explained by the fact that these patients being already in hospital when the diphtheria appeared, an unusually early opportunity was afforded for dealing with it.

There are certain cases of so malignant a character from the first that no treatment will probably ever be able to cope with them. But taking all cases together it seems probable that Behring's hope that the mortality may be reduced to 5 per cent. will be fully realised when the public become alive to the paramount importance of having the treatment commenced at the outset of the disease

There are many able workers in the field of Bacteriology whose names time does not permit me to mention, and to whose important labours I cannot refer; and even those researches of which I have spoken have been, of course, most inadequately dealt with. I feel this especially with regard to Pasteur, whose work shines out more brightly the more his writings are perused.

I have lastly to bring before you a subject which, though not bacteriological, has intimate relations with bacteria. If a drop of blood is drawn from the finger by a prick with a needle and examined microscopically between two plates of glass, there are seen in it minute solid elements of two kinds, the one pale orange bi-concave discs, which, seen in mass, give the red colour to the vital fluid, the other more or less granular spherical masses of the soft material called protoplasm, destitute of colour, and therefore called the colourless or white corpuscles. It has been long known that if the microscope was placed at such a distance from a fire as to have the temperature of the human body, the white corpuscles might be seen to put out and retract little processes or pseudopodia, and by their means crawl over the surface of the glass, just like the extremely low forms of animal life termed, from this faculty of changing their form, amœbæ. It was a somewhat weird spectacle, that of seeing what had just before been constituents of our own blood moving about like independent creatures. Yet there was nothing in this inconsistent with what we knew of the fixed components of the animal frame. For example, the surface of a frog's tongue is covered with a layer of cells, each of which is provided with two or more lashing filaments or cilia, and those of all the cells acting in concert cause a constant flow of fluid in a definite direction over the organ. If we gently scrape the surface of the animal's tongue, we can detach some of these ciliated cells; and on examining them with the microscope in a drop of water, we find that they will continue for an indefinite time their lashing movements, which are just as much living or vital in their character as the writhings of a worm. And as I observed many years ago, these detached cells behave under the influence of a stimulus just like parts connected with the body, the movements of the cilia being excited to greater activity by gentle stimulation, and thrown into a state of temporary inactivity when the irritation was more severe. Thus each constituent element of our bodies may be regarded as in one sense an independent living being, though all work together in marvellous harmony for the good of the body politic. The independent movements of the white corpuscles outside the body were therefore not astonishing; but they long remained matters of mere curiosity. Much interest was called to them by the observation of the German pathologist Cohnheim that in some inflammatory conditions they passed through the pores in the walls of the finest blood-vessels, and thus escaped into the interstices of the surrounding tissues. Cohnheim attributed their transit to the pressure of the blood. But why it was that, though larger than the red corpuscles, and containing a nucleus which the red ones have not, they alone passed through the pores of the vessels, or why it was that this emigration of the white corpuscles occurred abundantly in some inflammations and was absent in others, was quite unexplained.

These white corpuscles, however, have been invested with extraordinary new interest by the researches of the Russian naturalist and pathologist, Metchnikoff. He observed that, after passing through the walls of the vessels, they not only crawl about like amœbæ, but, like them, receive nutritious materials into their soft bodies and digest them. It is thus that the effete materials of a tadpole's tail are got rid of; so that they play a most important part in the function of absorption.

But still more interesting observations followed. He found

that a microscopic crustacean, a kind of water-flea, was liable to be infested by a fungus which had exceedingly sharp-pointed spores. These were apt to penetrate the coats of the creature's intestine, and project into its body cavity. No sooner did this occur with any spore than it became surrounded by a group of the cells which are contained in the cavity of the body and correspond to the white corpuscles of our blood. These proceeded to attempt to devour the spore; and if they succeeded, in every such case the animal was saved from the invasion of the parasite. But if the spores were more than could be disposed of by the devouring cells (phagocytes, as Metchnikoff termed them), the water-flea succumbed.

Starting from this fundamental observation, he ascertained that the microbes of infective diseases are subject to this same process of devouring and digestion, carried on both by the white corpuscles and by cells that line the blood-vessels. And by a long series of most beautiful researches he has, as it appears to me, firmly established the great truth that phagocytosis is the main defensive means possessed by the living body against the invasions of its microscopic foes. The power of the system to produce antitoxic substances to counteract the poisons of microbes is undoubtedly in its own place of great importance. But in the large class of cases in which animals are naturally refractory to particular infective diseases the blood is not found to yield any antitoxic element by which the natural immunity can be accounted for. Here phagocytosis seems to be the sole defensive agency. And even in cases in which the serum does possess antitoxic, or, as it would seem in some cases, germicidal properties, the bodies of the dead microbes must at last be got rid of by phagocytosis, and some recent observations would seem to indicate that the useful elements of the serum may be, in part at least, derived from the digestive juices of the phagocytes. If ever there was a romantic chapter in pathology, it has surely been that of the story of phagocytosis.

I was myself peculiarly interested by these observations of Metchnikoff's, because they seemed to me to afford clear explanation of the healing of wounds by first intention under circumstances before incomprehensible. This primary union was sometimes seen to take place in wounds treated with water-dressing—that is to say, a piece of wet lint covered with a layer of oiled-silk to keep it moist. This, though cleanly when applied, was invariably putrid within twenty-four hours. The layer of blood between the cut surfaces was thus exposed at the outlet of the wound to a most potent septic focus. How was it prevented from putrefying, as it would have done under such influence if, instead of being between divided living tissues, it had been between plates of glass or other indifferent material? Pasteur's observations pushed the question a step further. It now was, How were the bacteria of putrefaction kept from propagating in the decomposable film? Metchnikoff's phagocytosis supplied the answer. The blood between the lips of the wound became rapidly peopled with phagocytes, which kept guard against the putrefactive microbes, and seized them as they endeavoured to enter.

If phagocytosis was ever able to cope with septic microbes in so concentrated and intense a form, it could hardly fail to deal effectually with them in the very mitigated condition in which they are present in the air. We are thus strongly confirmed in our conclusion that the atmospheric dust may safely be disregarded in our operations; and Metchnikoff's researches, while they have illumined the whole pathology of infective diseases, have beautifully completed the theory of antiseptic treatment in surgery.

I might have taken equally striking illustrations of my theme from other departments in which microbes play no part. In fact, any attempt to speak of all that the art of healing has borrowed from science and contributed to it during the past half-century, would involve a very extensive dissertation on pathology and therapeutics. I have culled specimens from a wide field; and I only hope that in bringing them before you I have not overstepped the bounds of what is fitting before a mixed company. For many of you my remarks can have had little, if any, novelty; for others they may perhaps possess some interest as showing that Medicine is no unworthy ally of the British Association; that, while her practice is ever more and more based on science, the ceaseless efforts of her votaries to improve what has been fittingly designated *Quæ prosunt omnibus artes*, are ever adding largely to the sum of abstract knowledge.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. J. J. THOMSON, F.R.S., PRESIDENT OF THE SECTION.

THERE is a melancholy reminiscence connected with this meeting of our Section, for when the British Association last met in Liverpool the chair in Section A was occupied by Clerk-Maxwell. In the quarter of a century which has elapsed since that meeting, one of the most important advances made in our science has been the researches which, inspired by Maxwell's view of electrical action, confirmed that view, and revolutionised our conception of the processes occurring in the Electro-magnetic field. When the Association last met in Liverpool Maxwell's view was almost without supporters, to-day its opponents are fewer than its supporters then. Maxwell's theory, which is the development and extension of Faraday's, has not only affected our way of regarding the older phenomena of electricity, it has, in the hands of Hertz and others, led to the discovery of whole regions of phenomena previously undreamt of. It is sad to think that his premature death prevented him from reaping the harvest he had sown. His writings are, however, with us, and are a storehouse to which we continually turn, and never, I think, without finding something valuable and suggestive.

> "Thus ye teach us day by day,
> Wisdom, though now far away."

The past year has been rich in matters of interest to physicists. In it has occurred the jubilee of Lord Kelvin's tenure of the Professorship of Natural Philosophy at the University of Glasgow. Some of us were privileged to see this year at Glasgow an event unprecedented in the history of physical science in England, when congratulations to Lord Kelvin on the jubilee of his professorship were offered by people of every condition and country. Every scientific society and every scientific man is Lord Kelvin's debtor; but no society and no body of men owe him a greater debt than Section A of the British Association; he has done more for this Section than any one else, he has rarely missed its meetings, he has contributed to the Section papers which will make its proceedings imperishable, and by his enthusiasm he has year by year inspired the workers in this Section to renew with increased vigour their struggles to penetrate the secrets of nature. Long may we continue to receive from him the encouragement and assistance which have been so freely given for the past half-century.

By the death of Sir W. R. Grove, the inventor of Grove's cell, we have lost a physicist whose name is a familiar one in every laboratory in the world. Besides the Grove cell, we owe to him the discovery of the gas battery, and a series of researches on the electrical behaviour of gases, whose importance is only now beginning to be appreciated. His essay on the correlation of the physical forces had great influence in promoting that belief in the unity of the various branches of physics which is one of the characteristic features of modern natural philosophy.

In the late Prof. Stoletow, of Moscow, we have lost the author of a series of most interesting researches on the electrical properties of gases illuminated by ultra-violet light, researches which, from their place of publication, are, I am afraid, not so well known in this country as they deserve to be.

As one who unfortunately of late years has had only too many opportunities of judging of the teaching of science in our public and secondary schools, I should like to bear testimony to the great improvement which has taken place in the teaching of physics in these schools during the past ten years. The standard attained in physics by the pupils of these schools is increasing year by year, and great credit is due to those by whose labours this improvement has been accomplished. I hope I may not be considered ungrateful if I express the opinion that in the zeal and energy which is now spent in the teaching of physics in schools, there may lurk a temptation to make the pupils cover too much ground. You may by careful organisation and arrangement ensure that boys shall be taken over many branches of physics in the course of a short time; it is indeed not uncommon to find boys of seventeen or eighteen who have compassed almost the whole range of physical subjects. But although you may increase the rate at which information is acquired, you cannot increase in anything like the same proportion the rate at which the subject is assimilated, so as to become a means of strengthening the mind and a permanent mental endowment when the facts have long been forgotten.

Physics can be taught so as to be a subject of the greatest possible educational value, but when it is so it is not so much because the student acquires a knowledge of a number of interesting and important facts, as by the mental training the study affords in, as Maxwell said, "bringing out theoretical knowledge to bear on the objects and the objects on our theoretical knowledge." I think this training can be got better by going very slowly through such a subject as mechanics, making the students try innumerable experiments of the simplest and, what is a matter of importance in school teaching, of the most inexpensive kind, but always endeavouring to arrive at numerical results, rather than by attempting to cover the whole range of mechanics, light, heat, sound, electricity, and magnetism. I confess I regret the presence in examinations intended for school boys of many of these subjects.

I think, too, that in the teaching of physics at our universities, there is perhaps a tendency to make the course too complex and too complete. I refer especially to the training of those students who intend to become physicists. I think that after a student has been trained to take accurate observations, to be alive to those pitfalls and errors to which all experiments are liable, mischief may in some cases be done if, with the view of learning a knowledge of methods, he is kept performing elaborate experiments, the results of which are well known. It is not given to many to wear a load of learning lightly as a flower. With many students a load of learning, especially if it takes a long time to acquire, is apt to crush enthusiasm. Now, there is, I think, hardly any quality more essential to success in physical investigations than enthusiasm. Any investigation in experimental physics requires a large expenditure of both time and patience; the apparatus seldom, if ever, begins by behaving as it ought; there are times when all the forces of nature, all the properties of matter, seem to be fighting against us; the instruments behave in the most capricious way, and we appreciate Coutts Trotter's saying, that the doctrine of the constancy of nature could never have been discovered in a laboratory. These difficulties have to be overcome, but it may take weeks or months to do so, and, unless the student is enthusiastic, he is apt to retire disheartened from the contest. I think, therefore, that the preservation of youthful enthusiasm is one of the most important points for consideration in the training of physicists. In my opinion this can best be done by allowing the student, even before he is supposed to be acquainted with the whole of physics, to begin some original research of a simple kind under the guidance of a teacher who will encourage him and assist in the removal of difficulties. If the student once tastes the delights of the successful completion of an investigation, he is not likely to go back, and will be better equipped for investigating the secrets of nature than if, like the White Knight of "Alice in Wonderland," he commences his career knowing how to measure or weigh every physical quantity under the sun, but with little desire or enthusiasm to have anything to do with any of them. Even for those students who intend to devote themselves to other pursuits than physical investigation, the benefits derived from original investigation as a means of general education can hardly be over-estimated, the necessity it entails of independent thought, perseverance in overcoming difficulties, and the weighing of evidence gives it an educational value which can hardly be rivalled. We have to congratulate ourselves that, through the munificence of Mr. Ludwig Mond, in providing and endowing a laboratory for research, the opportunities for pursuing original investigations in this country have been greatly increased.

The discovery at the end of last year by Prof. Röntgen of a new kind of radiation from a highly exhausted tube through which an electric discharge is passing, has aroused an amount of interest unprecedented in the history of physical science. The effects produced *inside* such a tube by the kathode rays, the bright phosphorescence of the glass, the shadows thrown by opaque objects, the deflection of the rays by a magnet, have, thanks to the researches of Crookes and Goldstein, long been familiar to us, but it is only recently that the remarkable effects which occur outside such a tube have been discovered. In 1893, Lenard, using a tube provided with a window made of a very hin plate of aluminium, found that a screen impregnated with a solution of a phosphorescent substance became luminous if placed outside the tube in the prolongation of the line from the kathode through the aluminium window. He also found that photographic plates placed outside the tube in this line were affected, and electrified bodies were discharged; he also obtained by these rays photographs through plates of aluminium or quartz. He found that the rays were affected by a magnet, and regarded them as the prolongations of the kathode rays. This discovery was at the end of last year followed by that of Röntgen, who found that the region round the discharge tube is traversed by rays which affect a photographic plate after passing through substances such as aluminium or cardboard, which are opaque to ordinary light; which pass from one substance to another, without any refraction, and with but little regular reflection; and which are not affected by a magnet. We may, I think, for the purposes of discussion, conveniently divide the rays occurring in or near a vacuum tube traversed by an electric current into three classes, without thereby implying that they are necessarily distinctly different in physical character. We have (1) the kathode rays inside the tube, which are deflected by a magnet; (2) the Lenard rays outside the tube, which are also deflected by a magnet; and (3) the Röntgen rays, which are not, as far as is known, deflected by a magnet. Two views are held as to the nature of the kathode rays; one view is, that they are particles of gas carrying charges of negative electricity, and moving with great velocities which they have acquired as they travelled through the intense electric field which exists in the neighbourhood of the negative electrode. The phosphorescence of the glass is on this view produced by the impact of these rapidly moving charged particles, though whether it is produced by the mechanical violence of the impact, or whether it is due to an electro-magnetic impulse produced by the sudden reversal of the velocity of the negatively charged particle—whether, in fact, it is due to mechanical or electrical causes, is an open question. This view of the constitution of the kathode rays explains in a simple way the deflection of those rays in a magnetic field, and it has lately received strong confirmation from the results of an experiment made by Perrin. Perrin placed inside the exhausted tube a cylindrical metal vessel with a small hole in it, and connected this cylinder with the leaves of a gold-leaf electroscope. The kathode rays could, by means of a magnet, be guided so as either to pass into the cylinder through the aperture, or turned quite away from it. Perrin found that when the kathode rays passed into the cylinder the gold leaf of the electroscope diverged, and had a negative charge, showing that the bundle of kathode rays enclosed by the cylinder had a charge of negative electricity. Crookes had many years ago exposed a disc connected with a gold-leaf electroscope to the bombardment of the kathode rays, and found that the disc received a slight *positive* charge; with this arrangement, however, the charged particles had to give up their charges to the disc if the gold leaves of the electroscope were to be affected, and we know that it is extremely difficult, if not impossible, to get electricity out of a charged gas merely by bringing the gas in contact with a metal. Lord Kelvin's electric strainers are an example of this. It is a feature of Perrin's experiment that since it acts by induction, the indications of the electroscope are independent of the communication of the charges of electricity from the gas to the cylinder, and since the kathode rays fall on the inside of the cylinder, the electroscope would not be affected, even if there were such an effect as is produced when ultra-violet light falls upon the surface of an electro-negative metal when the metal acquires a positive charge. Since any such process cannot affect the total amount of electricity inside the cylinder, it will not affect the gold leaves of the electroscope; in fact, Perrin's experiments prove that the kathode rays carry a charge of negative electricity.

The other view held as to the constitution of the kathode rays is that they are waves in the ether. It would seem difficult to account for the result of Perrin's experiment on this view, and also I think very difficult to account for the magnetic deflection of the rays. Let us take the case of a uniform magnetic field: the experiments which have been made on the magnetic deflection of these rays seem to make it clear that in a magnetic field which is sensibly uniform, the path of these rays is curved; now if these rays were due to ether waves, the curvature of the path would show that the velocity of propagation of these waves varied from point to point of the path. That is, the velocity of propagation of these waves is not only affected by the magnetic field, it is affected differently at different parts of the field. But in a uniform field what is there to differentiate one part from another, so as to account for the variability of the velocity of wave propagation in such a field? The curvature of the path in a uniform field could not be accounted for by supposing that the velocity of this wave motion

depended on the strength of the magnetic field, or that the magnetic field, by distorting the shape of the boundary of the negative dark space, changed the direction of the wave front, and so produced a deflection of the rays. The chief reason for supposing that the kathode rays are a species of wave motion is afforded by Lenard's discovery, that when the kathode rays in a vacuum tube fall on a thin aluminium window in the tube, rays having similar properties are observed on the side of the window outside the tube; this is readily explained on the hypothesis that the rays are a species of wave motion to which the window is partially transparent, while it is not very likely that particles of the gas in the tube could force their way through a piece of metal. This discovery of Lenard's does not, however, seem to me incompatible with the view that the kathode rays are due to negatively charged particles moving with high velocities. The space outside Lenard's tube must have been traversed by Röntgen rays, these would put the surrounding gas in a state in which a current would be readily started in the gas if any electromotive force acted upon it. Now, though the metal window in Lenard's experiments was connected with the earth, and would, therefore, screen off from the outside of the tube any effect arising from slow electrostatic changes in the tube, it does not follow that it would be able to screen off the electrostatic effect of charged particles moving to and from the tube with very great rapidity. For in order to screen off electrostatic effects, there must be a definite distribution of electrification over the screen; changes in this distribution, however, take a finite time, which depends upon the dimensions of the screen and the electrical conductivity of the material of which it is made. If the electrical changes in the tube take place at above a certain rate, the distribution of electricity on the screen will not have time to adjust itself, and the screen will cease to shield off all electrostatic effects. Thus the very rapid electrical changes which would take place if rapidly moving charged bodies were striking against the window, might give rise to electromotive forces in the region outside the window, and produce convection currents in the gas which has been made a conductor by the Röntgen rays. The Lenard rays would thus be analogous in character to the kathode rays, both being convective currents of electricity. Though there are some points in the behaviour of these Lenard rays which do not admit of a very ready explanation from this point of view, yet the difficulties in its way seem to me considerably less than that of supposing that a wave in the ether can change its velocity when moving from point to point in a uniform magnetic field.

I now pass on to the consideration of the Röntgen rays. We are not yet acquainted with any crucial experiment which shows unmistakably that these rays are waves of transverse vibration in the ether, or that they are waves of normal vibration, or indeed that they are vibrations at all. As a working hypothesis, however, it may be worth while considering the question whether there is any property known to be possessed by these rays which is not possessed by some form or other of light. The many forms of light have in the last few months received a noteworthy addition by the discovery of M. Becquerel of an invisible radiation, possessing many of the properties of the Röntgen rays, which is emitted by many fluorescent substances, and to an especially marked extent by the uranium salts. By means of this radiation, which, since it can be polarised, is unquestionably light, photographs through opaque substances similar to, though not so beautiful as, those obtained by means of Röntgen rays, can be taken, and, like the Röntgen rays, they cause an electrified body on which they shine to lose its charge, whether this be positive or negative.

The two respects in which the Röntgen rays differ from light is in the absence of refraction and perhaps of polarisation. Let us consider the absence of refraction first. We know cases in which special rays of the spectrum pass from one substance to another without refraction; for example, Kundt showed that gold, silver, copper allow some rays to pass through them without bending, while other rays are bent in the wrong direction. Pflüger has lately found that the same is true for some of the aniline dyes when in a solid form. In addition to this, the theory of dispersion of light shows that there will be no bending when the frequency of the vibration is very great. I have here a curve taken from a paper by Helmholtz, which shows the relation between the refractive index and the frequency of vibration for a substance whose molecules have a natural period of vibration, and one only; the frequency of this vibration is represented by OK in the diagram. The refractive index increases with the frequency of the light until the latter is equal to the frequency of the natural vibration of the substance; the refractive index then diminishes, becomes less than unity, and finally approaches unity, and is practically equal to it when the frequency of the light greatly exceeds that of the natural vibration of the molecule Helmholtz's results are obtained on the supposition that a molecule of the refracting substance consists of a pair of oppositely electrified atoms, and that the specific inductive capacity of the medium consists of two parts, one due to the ether, the other to the setting of the molecules along the lines of electric force.

Starting from this supposition we can easily see without mathematical analysis that the relation between the refractive index and the frequency must be of the kind indicated by the curve. Let us suppose that an electromotive force of given amplitude acts on this mixture of molecules and ether, and let us start with the frequency of the external electromotive force less than that of the free vibrations of the molecules: as the period of the force approaches that of the molecules, the effect of the force in pulling the molecules into line will increase; thus the specific inductive capacity, and therefore the refractive index increases with the frequency of the external force; the effect of the force on the orientation of the molecules will be greatest when the period of the force coincides with that of the molecules. As long as the frequency of the force is less than that of the molecules, the external field tends to make the molecules set so as to increase the specific inductive capacity of the mixture; as soon, however, as the frequency of the force exceeds that of the molecules, the molecules, if there are no viscous forces, will all topple over and point so as to make the part of the specific inductive capacity due to the molecules of opposite sign to that due to the ether. Thus, for frequencies greater than than of the molecules, the specific inductive capacity will be less than unity. When the frequency of the force only slightly exceeds that of the molecules, the effect of the external field on the molecules is very great, so that if there are a considerable number of molecules, the negative part of the specific inductive capacity due to the molecules may be greater than the positive part due to the ether, so that the specific inductive capacity of the mixture of molecules and ether would be negative; no waves of this period could then travel through the medium, they would be totally reflected from the surface.

As the frequency of the force gets greater and greater, its effect in making the molecules set will get less and less, but the waves will continue to be totally reflected until the negative part of the specific inductive capacity due to the molecules is just equal to the positive part due to the ether. Here the refractive index of the mixture is zero. As the frequency of the force increases, its effect on the molecules gets less and less, so that the specific inductive capacity continually approaches that due to the ether alone, and practically coincides with it as soon as the frequency of the force is a considerable multiple of that of the molecules. In this case both the specific inductive capacity and the refractive index of the medium are the same as that of the ether, and there is consequently no refraction. Thus the absence of refraction, instead of being in contradiction to the Röntgen rays, being a kind of light, is exactly what we should expect if the wave length of the light were exceedingly small.

The other objection to these rays being a kind of light is, that there is no very conclusive evidence of the existence of polarisation. Numerous experiments have been made on the difference between the absorption of these rays by a pair of tourmaline plates when their axes are crossed or parallel. Many observers have failed to observe any difference at all between the absorption in the two cases. Prince Galitzine and M. de Karnojitsky, by a kind of cumulative method, have obtained photographs which seem to show that there is a slightly greater absorption when the axes are crossed than there is when the axes are parallel. There can, however, be no question that the effect, if it exists at all, is exceedingly small compared with the corresponding effect for visible light. Analogy, however, leads us to expect that to get polarisation effects we must use, in the case of short waves, polarisers of a much finer structure than would be necessary for long ones. Thus a wire bird-cage will polarise long electrical waves, but will have no effect on visible light. Rubens and Du Bois made an instrument which would polarise the infra-red rays by winding very fine wires very close together on a framework; this arrangement,

however, was too coarse to polarise visible light. Thus, though the structure of the tourmaline is fine enough to polarise the visible rays, it may be much too coarse to polarise the Röntgen rays if these have exceedingly small wave-lengths. As far as our knowledge of these rays extends, I think we may say that though there is no direct evidence that they are a kind of light, there are no properties of the rays which are not possessed by some variety of light.

It is clear that if the Röntgen rays are light rays, their wave-lengths are of an entirely different order to those of visible light. It is perhaps worth notice that on the electro-magnetic theory of light we might expect two different types of vibration if we suppose that the atoms in the molecule of the vibrating substance carried electrical charges. One set of vibrations would be due to the oscillations of the bodies carrying the charges, the other set to the oscillation of the charges on these bodies. The wave-length of the second set of vibrations would be commensurate with molecular dimensions; Can these vibrations be the Röntgen rays? If so, we should expect them to be damped with such rapidity as to resemble electrical impulses rather than sustained vibrations.

If we turn from the rays themselves to the effect they produce, we find that the rays alter the properties of the substances through which they are passing. This change is most apparent in the effects produced on the electrical properties of the substances. A gas, for example, while transmitting these rays is a conductor of electricity. It retains its conducting properties for some little time after the rays have ceased to pass through it, but Mr. Rutherford and I have lately found that the conductivity is destroyed if a current of electricity is sent through the Röntgenised gas. The gas in this state behaves in this respect like a very dilute solution of an electrolyte. Such a solution would cease to conduct after enough electricity had been sent through it to electrolyse all the molecules of the electrolyte. When a current is passing through a gas exposed to the rays, the current destroys and the rays produce the structure which gives conductivity to the gas; when things have reached a steady state the rate of destruction by the current must equal the rate of production by the rays. The current can thus not exceed a definite value, otherwise more of the conducting gas would be destroyed than is produced.

This explains the very characteristic feature that in the passage of electricity through gases exposed to Röntgen rays, the current, though at first proportional to the electromotive force, soon reaches a value where it is almost constant and independent of the electromotive force, and we get to a state when a tenfold increase in the electromotive force only increases the current by a few per cent. The conductivity under the Röntgen rays varies greatly from one gas to another, the halogens and their gaseous compounds, the compounds of sulphur, and mercury vapour, are among the best conductors. It is worthy of note that those gases which are the best conductors when exposed to the rays are either elements, or compounds of elements, which have in comparison with their valency very high refractive indices.

The conductivity conferred by the rays on a gas is not destroyed by a considerable rise in temperature; it is, for example, not destroyed if it be sucked through metal tubing raised to a red heat. The conductivity is, however, destroyed if the gas is made to bubble through water, it is also destroyed if the gas is forced through a plug of glass wool. This last effect seems to indicate that the structure which confers conductivity on the gas is of a very coarse kind, and we get confirmation of this from the fact that a very thin layer of gas exposed to the Röntgen rays does not conduct nearly so well as a thicker one. I think we have evidence from other sources that electrical conduction is a process that requires a considerable space—a space large enough to enclose a very large number of molecules.

Thus Koller found that the specific resistances of petroleum, turpentine, and distilled water, when determined from experiments made with very thin layers of these substances, was very much larger than when determined from experiments with thicker layers. Even in the case of metals there is evidence that the metal has to be of appreciable size if it is to conduct electricity. The theory of the scattering of light by small particles shows that, if we assume the truth of the electromagnetic theory of light, the effects should be diffeıent according as the small particles are insulators or conductors. When the small particles are non-conductors, theory and experiment concur in showing that the direction of complete polarisation for the scattered light is at right angles to the direction of the incident light, while if the small particles are conductors, theory indicates that the direction of complete polarisation makes an angle of 60° with the incident light. This result is not, however, confirmed by the experiments made by Prof. Threlfall on the scattering of light by very small particles of gold. He found that the gold scattered the light in just the same way as a non-conductor, giving complete polarisation at right angles to the incident light. This would seem to indicate that those very finely divided metallic particles no longer acted as conductors. Thus there seems evidence that in the case of conduction through gases, through badly conducting liquids and through metals, electric conduction is a process which requires a very considerable space and aggregations of large numbers of molecules. I have not been able to find any direct experimental evidence as to whether the same is true for electrolytes. Experiments on the resistance of thin layers of electrolytes would be of considerable interest, as according to one widely-accepted view of electrolysis conduction through electrolytes, so far from being effected by aggregations of molecules, takes place by means of the ion, a structure simpler than that of the molecule, so that if this represents the process of electrolytic conduction, there would not seem room for the occurrence of an effect which occurs with every other kind of conduction.

In this building it is only fitting that some reference should be made to the question of the movement of the ether. You are all doubtless acquainted with the heroic attempts made by Prof. Lodge to set the ether in motion, and how successfully the ether resisted them. It seems to be conclusively proved that a solid body in motion does not set in motion the ether at an appreciable distance outside it; so that if the ether is disturbed at all in such a case, the disturbance is not comparable with that produced by a solid moving through an incompressible fluid, but must be more analogous to that which would be produced by the motion through the liquid of a body of very open structure, such as a piece of wire netting, where the motion of the fluid only extends to a distance comparable with the diameter of the wire, and not with that of the piece of netting. There is another class of phenomena relating to the movement of the ether which is, I think, deserving of consideration, and that is the effect of a varying electro-magnetic field in setting the ether in motion. I do not remember to have seen it pointed out that the electro-magnetic theory of light implicitly assumes that the ether is not set in motion even when acted on by mechanical forces. On the electro-magnetic theory of light such forces do exist, and the equations used are only applicable when the ether is at rest. Consider, for example, the case of a plane electric wave travelling through the ether. We have parallel to the wave-front a varying electric polarisation, which on the theory is equivalent to a current; at right-angles to this, and also in the wave-front, we have a magnetic force. Now, when a current flows through a medium in a magnetic field there is a force acting on the medium at right-angles to the plane, which is parallel both to the current and to the magnetic force; there will thus be a mechanical force acting on each unit volume of the ether when transmitting an electric wave, and since this force is at right-angles to the current and to the magnetic force, it will be in the direction in which the wave is propagated. In the electro-magnetic theory of light, however, we assume that this force does not set the ether in motion, as unless we made this assumption we should have to modify our equations, as the electro-magnetic equations are not the same in a moving field as in a field at rest. In fact, a complete discussion of the transmission of electro-magnetic disturbances requires a knowledge of the constitution of the ether which we do not possess. We now assume that the ether is not set in motion by an electro-magnetic wave. If we do not make this assumption, we must introduce into our equation quantities representing the components of the velocity of the ether, and unless we know the constitution of the ether, so as to be able to deduce these velocities from the forces acting on it, there will be in the equations of the electro-magnetic field more unknown quantities than we have equations to determine. It is, therefore, a very essential point in electro-magnetic theory to investigate whether or not there is any motion of the ether in a varying electro-magnetic field. We have at the Cavendish Laboratory, using Prof. Lodge's arrangement of interference fringes, made some experiments to see if we could detect any movement of the ether in the neighbourhood of an electric vibrator, using the spark which starts the vibrations as the source of light. The movement of the ether, if it exists, will

be oscillatory, and with an undamped vibrator the average velocity would be zero; we used, therefore, a heavily damped vibrator, with which the average velocity might be expected to be finite. The experiments are not complete, but so far the results are entirely negative. We also tried by the same method to see if we could detect any movement of the ether in the neighbourhood of a vacuum-tube emitting Röntgen rays, but could not find any trace of such a movement. Prof. Threlfall, who independently tried the same experiment, has, I believe, arrived at the same conclusion.

Unless the ether is immovable under the mechanical forces in a varying electro-magnetic field, there are a multitude of phenomena awaiting discovery. If the ether does move, then the velocity of transmission of electrical vibrations, and therefore of light, will be affected by a steady magnetic field. Such a field, even if containing nothing but ether, will behave towards light like a crystal, and the velocity of propagation will depend upon the direction of the rays. A similar result would also hold in a steady electric field. We may hope that experiments on these and similar points may throw some light on the properties of that medium which is universal, which plays so large a part in our explanation of physical phenomena, and of which we know so little.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY DR. LUDWIG MOND, F.R.S., PRESIDENT OF THE SECTION.

IN endeavouring to fix upon a suitable theme for the address I knew you would to-day expect from me, I have felt that I ought to give due consideration to the interests which tie this magnificent city of Liverpool, whose hospitality we enjoy this week, to Section B. of the British Association.

I have therefore chosen to give you a brief history of the manufacture of chlorine, with the progress of which this city and its neighbourhood have been very conspicuously and very honourably connected, not only as regards quantity—I believe this neighbourhood produces to-day nearly as much chlorine as the rest of this world together—but more particularly by having originated, worked out, and carried into practice several of the most important improvements ever introduced into this manufacture. I was confirmed in my choice by the fact that this manufacture has been influenced and perfected in an extraordinary degree by the rapid assimilation and application of the results of purely scientific investigations, and of new scientific theories, and offers a very remarkable example of the incalculable value to our commercial interests of the progress of pure science.

The early history of chlorine is particularly interesting, as it played a most important *rôle* in the development of chemical theories. There can be no doubt that the Arabian alchemist Geber, who lived eleven hundred years ago, must have known that "Aqua Regia," which he prepared by distilling a mixture of salt, nitre, and vitriol, gave off, on heating, very corrosive, evil-smelling, greenish-yellow fumes; and all his followers throughout a thousand years must have been more or less molested by these fumes whenever they used Aqua Regia, the one solvent of the gold they attempted so persistently to produce.

But it was not until 1774 that the great Swedish chemist Scheele succeeded in establishing the character of these fumes. He discovered that on heating manganese with muriatic acid he obtained fumes very similar to those given off by "Aqua Regia," and found that these fumes constituted a permanent gas of yellowish-green colour, very pungent odour, very corrosive, very irritating to the respiratory organs, and which had the power of destroying organic colouring matters.

According to the views prevalent at the time, Scheele considered that the manganese had removed phlogiston from the muriatic acid, and he consequently called the gas dephlogisticated muriatic acid.

When, during the next decade, Lavoisier successfully attacked, and after a memorable struggle completely upset the phlogiston theory, and laid the foundations of our modern chemistry, Berthollet, the eminent "father" of physical chemistry—the science of to-day—endeavoured to determine the place of Scheele's gas in the new theory. Lavoisier was of opinion that all acids, including muriatic acid, contain oxygen. Berthollet found that a solution of Scheele's gas in water, when exposed to the sunlight, gives off oxygen and leaves behind muriatic acid. He considered this as proof that this gas consists of muriatic acid and oxygen, and called it oxygenated muriatic acid.

In the year 1785 Berthollet conceived the idea of utilising the colour-destroying powers of this gas for bleaching purposes. He prepared the gas by heating a mixture of salt, manganese, and vitriol. He used a solution of the gas in water for bleaching, and subsequently discovered that the product obtained by absorbing the gas in a solution of caustic potash possessed great advantages in practice.

This solution was prepared as early as 1789, at the chemical works on the Quai de Javelle, in Paris, and is still made and used there under the name of "Eau de Javelle."

James Watt, whose great mind was not entirely taken up with that greatest of all inventions—his steam-engine—by which he has benefited the human race more than any other man, but who also did excellent work in chemistry—became acquainted in Paris with Berthollet's process, and brought it to Scotland. Here it was taken up with that energy characteristic of the Scotch, and a great stride forward was made when, in 1798, Charles Tennant, the founder of the great firm, which has only recently lapsed into the United Alkali Company, began to use milk of lime in place of the more costly caustic potash, in making a bleaching liquid; and a still greater advance was made when, in the following year, Tennant proposed to absorb the chlorine by hydrate of lime, and thus to produce a dry substance, since known under the name of bleaching powder, which allowed the bleaching powers of chlorine to be transported to any distance.

In order to give you a conception of the theoretical ideas prevalent at this time, I will read to you a passage from an interesting treatise on the art of bleaching published in 1799 by Higgins. In his chapter "On bleaching with the oxygenated muriatic acid, and on the methods of preparing it," he explains the theory of the process as follows:—

"Manganese is an oxyd, a metal saturated with oxygen gas. Common salt is composed of muriatic acid and an alkaline salt called soda, the same which barilla affords. Manganese has greater affinity to sulphuric acid than to its oxygen, and the soda of the salt greater affinity to sulphuric acid than to the muriatic acid gas; hence it necessarily follows that these two gases (or, rather, their gravitating matter) must be liberated from their former union in immediate contact with each other; and although they have but a weak affinity to one another, they unite in their nascent state, that is to say, before they individually unite to caloric, and separately assume the gaseous state; for oxygen gas and muriatic acid gas already formed will not unite when mixed, in consequence principally of the distance at which their respective atmospheres of caloric keep their gravitating particles asunder. The compound resulting from these two gases still retains the property of assuming the gaseous state, and is the oxygenated muriatic gas."

Interesting as these views may appear, considering the time they were published, you will notice that the *rôle* played by the manganese in the process, and the chemical nature of this substance, were not at all understood. The law of multiple proportions had not yet been propounded by John Dalton, and the researches of Berzelius on the oxides of manganese were only published thirteen years later, in 1812. The green gas we are considering was still looked upon as muriatic acid, to which oxygen had been added, in contradistinction to Scheele's view, who considered it as muriatic acid, from which something, viz. phlogiston, had been abstracted.

It was Humphry Davy who had, by a series of brilliant investigations, carried out in the laboratory of the Royal Institution between 1808 and 1810, accumulated fact upon fact to prove that the gas hitherto called oxygenated muriatic acid did not contain oxygen. He announced in an historic paper, which he read before the Royal Society on July 12, 1810, his conclusion that this gas was an elementary body, which in muriatic acid was combined with hydrogen, and for which he proposed the name "chlorine," derived from the Greek χλωρός, signifying "green," the colour by which the gas is distinguished.

The numerous communications which Humphry Davy made to the Royal Society on this subject form one of the brightest and most interesting chapters in the history of chemistry. They have recently been reprinted by the Alembic Society, and I cannot too highly recommend their study to the young students of our science.

Those who have followed the history of chemistry I need not remind how hotly and persistently Davy's views were combated by a number of the most eminent chemists of his time, led by

Berzelius himself; how long the chlorine controversy divided the chemical world; how triumphantly Davy emerged from it; how completely his views were recognised; and how very instrumental they have been in advancing theoretical chemistry.

The hope, however, which Davy expressed in that same historic paper, "that these new views would perhaps facilitate one of the greatest problems in economical chemistry, the decomposition of the muriates of soda and potash," was not to be realised so soon. Although it had changed its name, chlorine was still for many years manufactured by heating a mixture of salt, manganese, and sulphuric acid in leaden stills, as before.

This process leaves a residue consisting of sulphate of soda and sulphate of manganese, and for some time attempts were made to recover the sulphate of soda from these residues, and to use it for the manufacture of carbonate of soda by the Le Blanc process. On the other hand, the Le Blanc process, which had been discovered and put into practice almost simultaneously with Berthollet's chlorine process, decomposed salt by sulphuric acid, and sent the muriatic acid evolved into the atmosphere, causing a great nuisance to the neighbourhood.

Naturally, therefore, when Mr. William Gossage had succeeded in devising plant for condensing this muriatic acid, the manufacturers of chlorine reverted to the original process of Scheele, and heated manganese with the muriatic acid thus obtained. Since then the manufacture of chlorine has become a bye-product of the manufacture of soda by the Le Blanc process, and remained so till very recently.

For a great many years the muriatic acid was allowed to act upon native ores of manganese in closed vessels of earthenware or stone, to which heat could be applied, either externally or internally. These native manganese ores, containing only a certain amount of peroxide, converted only a certain percentage of the muriatic acid employed into free chlorine, the rest combining with the manganese and iron contained in the ore, and forming a brown and very acid solution, which it was a great difficulty for the manufacturer to get rid of. Consequently, many attempts were made to regenerate peroxide of manganese from these waste liquors, so as to use it over again in the production of chlorine.

These, however, for a long time remained unsuccessful, because the exact conditions for super-oxidising the protoxide of manganese by means of atmospheric air were not yet known.

Meantime, viz. in 1845, Mr. Dunlop introduced into the works created by his grandfather, Mr. Charles Tennant, at St. Rollox, a new and very interesting method for producing chlorine, which was in a certain measure a return to the process used by the alchemists.

Indeed, the first part of this process consisted in decomposing a mixture of salt and nitre with oil of vitriol—a reaction that had been made use of for so many centuries! The chlorine so obtained is, however, not pure, but a mixture of chlorine with oxides of nitrogen and hydrochloric acid, which Mr. Dunlop had to find means to eliminate.

For separating the nitrous oxides, Mr. Dunlop adopted the method introduced twenty years before by the great Gay-Lussac in connection with vitriol-making, viz. absorption by sulphuric acid, and the nitro-sulphuric acid thus formed he also utilised in the same way as that obtained from the towers which still bear Gay-Lussac's illustrious name, viz. by using it in the vitriol process in lieu of nitric acid. He then freed his chlorine gas from hydrochloric acid by washing with water, and so obtained it pure. This process possessed two distinct advantages: (1) it yielded a very much larger amount of chlorine from the same amount of salt, and (2) the nitric acid, which was used for oxidising the hydrogen in the hydrochloric acid, was not lost, because the oxides of nitrogen to which it was reduced answered the purpose for which the acid itself had previously been employed. But this process was very limited in its application, as it could only be worked to the extent to which nitric acid was used in vitriol-making.

The process has been at work at St. Rollox for over fifty years, and, as far as I know, is there still in operation; but I am not aware that it has ever been taken up elsewhere.

Within the last few years, however, several serious attempts have been made to give to this process a wider scope by regenerating nitric acid from the nitro-sulphuric acid and employing it over and over again to convert hydrochloric acid into chlorine. Quite a number of patents have been taken out for this purpose, all employing atmospheric air for reconverting the nitrous oxides into nitric acid, and differing mainly in details of apparatus and methods of work, and several of these have been put to practical test on a fairly large scale in this neighbourhood, and also in Glasgow, Middlesbrough, and elsewhere. As I do not want to keep you here the whole afternoon, I have to draw the line somewhere as to what I shall include in this brief history of the manufacture of chlorine, and have had to decide to restrict myself to those methods which have actually attained the rank of manufacturing processes on a large scale. As none of the processes just referred to have attained that position, you will excuse me for not entering into further details respecting them.

Mr. Dunlop's process only produced a very small portion of the chlorine manufactured at that time at St. Rollox, the remainder being made, as before, from native manganese and muriatic acid, leaving behind the very offensive waste liquors I have mentioned before, which increased from year to year, and became more and more difficult to get rid of. The problem of recovering from these liquors the manganese in the form of peroxide Mr. Dunlop succeeded in solving in 1855.

He neutralised the free acid and precipitated the iron present by treating these liquors with ground chalk in the cold and settling out, and in later years, filter-pressing the precipitate, which left him a solution of chloride of manganese, mixed only with chloride of calcium. This was treated with a fresh quantity of milk of chalk, but this time under pressure in closed vessels provided with agitators and heated by steam, under which conditions all the manganese was precipitated as carbonate of manganese. This precipitate was filtered off and well drained, and was then passed on iron trays mounted on carriages through long chambers, in which it was exposed to hot air at a temperature of 300° C., the process being practically made continuous, one tray at the one end being taken out of these chambers, and a fresh tray being put in at the other end. One passage through these chambers sufficed to convert the carbonate of manganese into peroxide, which was used in place of, and in the same way as, the native manganese.

The whole of the residual liquors made at the large works at St. Rollox have been treated by this process with signal success for a long number of years. For a short time the process was discontinued in favour of the Weldon process (of which I have to speak next); but after two years Dunlop's process was taken up again, and, to the best of my knowledge, it is still in operation to this day. It has, however, just like Mr. Dunlop's first chlorine process, never left the place of its birth (St. Rollox), although it was for a period of over ten years without a rival.

In 1866, Mr. Walter Weldon patented a modification of a process proposed by Mr. William Gossage, in 1837, for recovering the manganese that had been used in the manufacture of chlorine. Mr. Gossage had proposed to treat the residual liquors of this manufacture by lime, and to oxidise the resulting protoxide of manganese by bringing it into frequent and intimate contact with atmospheric air. This process—and several modifications thereof subsequently patented—had been tried in various places without success. Mr. Weldon, however, did succeed in obtaining a very satisfactory result, possibly—even probably—because, not being a chemist, he did not add the equivalent quantity of lime to his liquor to precipitate the manganese, but used an excess. However, Mr. Weldon, if he was not a chemist at that time, was a man of genius and of great perseverance. He soon made himself a chemist, and having once got a satisfactory result, he studied every small detail of the reaction with the utmost tenacity until he had thoroughly established how this satisfactory result could be obtained on the largest scale with the greatest regularity and certainty.

He even went further, and added considerably to our theoretical knowledge of the character of manganese peroxide and similar peroxides by putting forward the view that these compounds possess the character of weak acids. He explained in this way the necessity for the presence of an excess of lime or other base if the oxidation of the precipitated protoxide of manganese by means of atmospheric air was to proceed at a sufficiently rapid rate. He pointed out that the product had to be considered as a manganite of calcium, a view which has since been thoroughly proved by the investigations of Goergen and others; and it is only fair to state that Weldon's process is not only a process for recovering the peroxide of manganese originally used, but that he introduced a new substance, viz. manganite of calcium, to be continuously used over and over again in the manufacture of chlorine.

Mr. Weldon had the good fortune that his ideas were taken

up with fervency by Colonel Gamble of St. Helens, and that Colonel Gamble's manager, Mr. F. Bramwell, placed all his experience as a consummate technical chemist and engineer at Mr. Weldon's disposal, and assisted him in carrying his ideas into practice. The result was that a process which many able men had tried in vain to realise for thirty years became in the hands of Mr. Weldon and his coadjutors within a few years one of the greatest successes achieved in manufacturing chemistry.

The Weldon process commences by treating the residual liquor with ground chalk or limestone, thus neutralising the free acid and precipitating any sulphuric acid and oxide of iron present. The clarified liquor is run into a tall cylindrical vessel, and milk of lime is added in sufficient quantity to precipitate all the manganese in the form of protoxide. An additional quantity of milk of lime, from one-fifth to one-third of the quantity previously used, is then introduced, and air passed through the vessel by means of an air-compressor. After a few hours all the manganese is converted into peroxide; the contents of the vessel are then run off; the mud, now everywhere known as "Weldon mud," is settled, and the clear liquor run to waste. The mud is then pumped into large closed stone stills, where it meets with muriatic acid, chlorine is given off, and the residual liquor treated as before.

You note that this process works without any manipulation, merely by the circulation of liquids and thick magmas which are moved by pumping machinery. As compared to older processes it also has the great advantage that it requires very little time for completing the cycle of operations, so that large quantities of chlorine can be produced by a very simple and inexpensive plant. These advantages secured for this process the quite unprecedented success that within a few years it was adopted, with a few isolated exceptions, by every large manufacturer of chlorine in the world; yet it possessed a distinct drawback, viz. that it produced considerably less chlorine from a given quantity of muriatic acid than either native manganese of good quality or Mr. Dunlop's recovered manganese. At that time, however, muriatic acid was produced as a bye-product of the Le Blanc process so largely in excess of what could be utilised that it was generally looked upon as a waste product of no value. Mr. Weldon himself was one of the very few who foresaw that this state of things could not always continue. The ammonia soda process was casting its shadow before it. Patented in 1838 by Messrs. Dyar and Hemming it was only after the lapse of thirty years (during which a number of manufacturing chemists of the highest standing had in vain endeavoured to carry it into practice) that this process was raised to the rank of a manufacturing process through the indomitable perseverance of Mr. Earnest Solvay of Brussels, and his clear perception of its practical and theoretical intricacies. A few years later, in 1872, Mr. Weldon already gave his attention to the problem of obtaining the chlorine of the salt used in this process in the form of muriatic acid. He proposed to recover the ammonia from the ammonium chloride obtained in this manufacture by magnesia instead of lime, thus obtaining magnesium chloride instead of calcium chloride, and to produce muriatic acid from this magnesium chloride by a process patented by Clemm in 1863, viz. by evaporating the solution, heating the residue in the presence of steam and condensing the acid vapours given off.

Strange to say, this same method had been patented by Mr. Ernest Solvay within twenty-fours before Mr. Weldon lodged his specification. It has been frequently tried with many modifications, but has never been found practicable. Soon afterwards Mr. Weldon, with the object of reducing the muriatic acid required by his first process, proposed to replace the lime in this process by magnesia, and so to produce a manganite of magnesia. After treating this with muriatic acid and liberating chlorine he proceeded to evaporate the residual liquors to dryness, during which operation all the chlorine they contain would be disengaged as hydrochloric acid and collected in condensers, while the dry residue, after being heated to dull redness in the presence of air, would be reconverted into manganite of magnesia.

This process was made the subject of long and extensive experiments at the works of Messrs. Gamble at St. Helens, but did not realise Mr. Weldon's expectations. It, however, led to some further interesting developments, to which I shall refer later on.

Those of you who were present at the last meeting of the British Association in this city will remember that this Section had the advantage of listening to a paper by Mr. Weldon on his chlorine process, and also to another highly interesting paper by Mr. Henry Deacon, of Widnes, "on a new chlorine process without manganese." And those of you who came with the then President of the Section (Prof. Roscoe) to Widnes to visit the works of Messrs. Gaskell, Deacon, and Co., will well remember that at these works they saw side by side Weldon's process and Deacon's process in operation, and no one present will have forgotten the thoughtful flashing eyes and impressive face of Mr. Deacon when he explained to his visitors the theoretical views he had formed as regards his process.

Mr. Deacon had made a careful study of thermo-chemistry, which had been greatly developed during the preceding decade by the painstaking, accurate, and comprehensive experiments of Julius Thomsen and of Berthelot, and had led the latter to generalisations, which, although not fully accepted by scientific men, have been of immense service to manufacturing chemistry.

Mr. Deacon came to the conclusion that if a mixture of hydrochloric acid with atmospheric air was heated in the presence of a suitable substance capable of initiating the interaction of these two gases by its affinity to both, it would to a very great extent be converted into chlorine with the simultaneous formation of steam, because the formation of steam from oxygen and hydrogen gives rise to the evolution of a considerably larger quantity of heat than the combination of hydrogen and chlorine. Mr. Deacon found that the salts of copper were a very suitable substance for this purpose, and took out a patent for this process in 1868. He entrusted the study of the theoretical and practical problems connected with this process to Dr. Ferdinand Hurter, who carried them out in a manner which will always remain memorable and will never be surpassed, as an example of the application of scientific methods to manufacturing problems, and which soon placed this beautiful and simple process on a sound basis as a manufacturing operation.

In the ordinary course of manufacture the major part—about two-thirds—of the hydrochloric acid is obtained mixed with air and a certain amount of steam, but otherwise very little contaminated. Instead of condensing the muriatic acid from this mixture of gases by bringing it into contact with water, Mr. Deacon passed it through a long series of cooling pipes to condense the steam, which of course absorbed hydrochloric acid, and formed a certain quantity of strong muriatic acid. The mixture of gases was then passed through an iron superheater to raise it to the required temperature, and thence through a mass of broken bricks impregnated with sulphate or chloride of copper contained in a chamber or cylinder called a decomposer, which was protected from loss of heat by being placed in a brick furnace kept sufficiently hot. In this apparatus from 50 to 60 per cent. of the hydrochloric acid in the mixture of gases was burnt to steam and chlorine. In order to separate this chlorine from the steam and the remaining hydrochloric acid the gases were washed with water, and subsequently with sulphuric acid. The mixture now consisted of nitrogen and oxygen, containing about 10 per cent. of chlorine gas, which could be utilised without any difficulty in the manufacture of bleach liquors and chlorate of potash, and which Mr. Deacon also succeeded in using for the manufacture of bleaching powder, by bringing it into contact in specially constructed chambers with large surfaces of hydrate of lime. Within recent years this latter object has been attained in a more expeditious and perfect manner by continuous mechanical apparatus (of which those constructed by Mr. Robert Hasenclever and Dr. Carl Langer have been the most successful), in which the hydrate of lime is transported in a continuous stream by single or double conveyers in an opposite direction to the current of dilute chlorine, and the bleaching powder formed delivered direct into casks, thereby avoiding the intensely disagreeable work of packing this offensive substance by hand.

Mr. Deacon's beautiful and scientific process thus involves still less movement of materials than the very simple process of Mr. Weldon, because in lieu of large volumes of liquids he only moves a current of gas through his apparatus, which requires a minimum of energy. The only raw material used for converting hydrochloric acid into chlorine is atmospheric air, the cheapest of all at our command. The hydrochloric acid which has not been converted into chlorine by the process is all obtained, dissolved in water, as muriatic acid, and is not lost, as in previous processes, but is still available to be converted into chlorine by other methods, or to be used for other purposes.

In spite of these distinct advantages, this process took a long time before it became adopted as widely as it undoubtedly deserved. This was mainly due to the fact that the economy in

the use of muriatic acid which it effected was at the time when the process was brought out, and for many years afterwards, no object to the majority of chlorine manufacturers, who were still producing more of this commodity than they could use. Moreover, there were other reasons. The plant required for this process, although so simple in principle, is very bulky in proportion to the quantity of chlorine produced, and as I have pointed out, the process only succeeded in converting about one-third of the hydrochloric acid produced into chlorine, the remainder being obtained as muriatic acid, which had in most instances to be converted into chlorine by the Weldon process; so that the Deacon process did not constitute an entirely self-contained method for this manufacture. This defect, of small moment as long as muriatic acid was produced in excessive quantities, was only remedied by an invention of Mr. Robert Hasenclever a short number of years ago; when by the rapid development of the ammonia soda process the previously existing state of things had been completely changed, and when, at least on the continent, muriatic acid was no longer an abundant and valueless bye-product, but, on the contrary, the alkali produced by the Le Blanc process had become a bye-product of the manufacture of chlorine. Mr. Hasenclever, in order to make the whole of the muriatic acid he produces available for conversion into chlorine by the Deacon process, introduces the liquid muriatic acid in a continuous stream into hot sulphuric acid contained in a series of stone vessels, through which he passes a current of air. He thus obtains a mixture of hydrochloric acid and air, well adapted for the Deacon process, the water of the muriatic acid remaining with the sulphuric acid, from which it is subsequently eliminated by evaporation. In this way the chlorine in the hydrochloric acid can be almost entirely obtained in its free state by the simplest imaginable means, and with the intervention of no other chemical agent than atmospheric air. Since their introduction the Deacon process has supplanted the Weldon process in nearly all the largest chlorine works in France and Germany, and is now also making very rapid progress in this country.

Mr. Weldon, when he decided to give up his manganite of magnesia process, by no means relaxed his efforts to work out a chlorine process which should utilise the whole of the muriatic acid. While working with manganite of magnesia he found that magnesia alone would answer the purpose without the presence of the peroxide of manganese. He obtained the assistance of M. Pechiney, of Salindres, and in conjunction with him worked out what has become known as the "Weldon-Pechiney" process, which was first patented in 1884.

This process consists in neutralising muriatic acid by magnesia, concentrating the solution to a point at which it does not yet give off any hydrochloric acid, and then mixing into it a fresh quantity of magnesia so as to obtain a solid oxychloride of magnesium. This is broken up into small pieces, which are heated up rapidly to a high temperature without contact with the heating medium, while a current of air is passing through them. The oxychloride of magnesium containing a large quantity of water, this treatment yields a mixture of chlorine and hydrochloric acid with air and steam, the same as the Deacon process, and this is treated in a very similar way to eliminate the steam and the acid from the chlorine. The acid condensed is, of course, treated with a fresh quantity of magnesia, so that the whole of the chlorine which it contains is gradually obtained in the free state.

The rapid heating to a high temperature of the oxychloride of magnesium without contact with the heating medium was an extremely difficult practical problem, which has been solved by M. Pechiney and his able assistant, M. Boulouvard, in a very ingenious and entirely novel way.

They lined a large wrought-iron box with fire-bricks, and built inside of this vertical fire-brick walls with small empty spaces between them, thus forming a number of very narrow chambers, so arranged that they could all be filled from the top of the box, and emptied from the bottom. These chambers they heated to a very high temperature by passing a gas flame through them, thus storing up in the brick walls enough heat to carry out and complete the decomposition of the magnesium oxychloride, with which the chamber was filled when hot enough.

Mr. Weldon himself called this apparatus a "baker's oven," in which trade certainly the same principle has been employed from time immemorial; but to my knowledge it had never before been used in any chemical industry. This process has been at work at M. Pechiney's large alkali works at Salindres, and is now at work in this country at the chlorate of potash works of Messrs. Allbright and Wilson, at Oldbury, a manufacture for which it offers special advantages. Mr. Weldon and M. Pechiney had expected that this process would become specially useful in connection with the ammonia soda process by preparing in the way proposed by Mr. Solvay and Mr. Weldon in 1872 a solution of magnesium chloride as a bye-product of this manufacture; but instead of obtaining muriatic acid from this solution by Clemm's process, to treat it by the new process, so as to obtain the bulk of the chlorine at once in the free state. But M. Pechiney did no more succeed than his predecessors in recovering the ammonia by means of magnesia in a satisfactory way.

Quite recently, however, it has been applied to obtain chlorine in connection with the ammonia soda process by Dr. Pick, of Czakowa, in Austria. He recovers the ammonia, as usual, by means of lime, and converts the solution of chloride of calcium, obtained by a process patented by Mr. Weldon in 1869, viz. by treatment with magnesia and carbonic acid under pressure, into chloride of magnesium with the formation of carbonate of lime. The magnesium chloride solution is then concentrated and treated by the Weldon-Pechiney process.

I have repeatedly referred during this brief history to the great change which has been brought about in the position of chlorine manufacture by the development of the ammonia soda process, and have pointed out that the muriatic acid which for a long time was the bye-product of the Le Blanc process, without value, thereby became gradually its main and most valuable product, while the alkali became its bye-product.

I have told you how, very early in the history of this process, Mr. Solvay and Mr. Weldon proposed means to provide for this contingency, and how Mr. Weldon continued to improve these means until the time of his death. Mr. Solvay, on his part, also followed up the subject with that tenacity and sincerity of purpose which distinguishes him; his endeavours being mainly directed to producing chlorine direct from the chloride of calcium running away from his works by mixing it with clay and passing air through the mixture at very high temperatures, thus producing chlorine and a silicate of calcium, which could be utilised in cement-making. The very high temperatures required prevented, however, this process from becoming a practical success.

I have already told you what a complicated series of operations Dr. Pick has lately resorted to in order to obtain the chlorine from this chloride of calcium. Yet the problem of obtaining chlorine as a bye-product of the ammonia soda process presents itself as a very simple one.

This process produces a precipitate of bicarbonate of soda and a solution of chloride of ammonium by treating natural brine, or an artificially made solution of salt, in which a certain amount of ammonia has been dissolved, with carbonic acid. In their original patent of 1838, Messrs. Dyar and Hemming proposed to evaporate this solution of ammonium chloride, and to distil the resulting dry product with lime to recover the ammonia. Now, all that seemed to be necessary to obtain the chlorine from this ammonium chloride was to substitute another oxide for lime in the distillation process, which would liberate the ammonia and form a chloride which, on treatment with atmospheric air would give off its chlorine and reproduce the original oxide. The whole of the reactions for producing carbonate of soda and bleaching powder from salt would thus be reduced to their simplest possible form; the solution of salt, as we obtain it in the form of brine direct from the soil, would be treated with ammonia and carbonic acid to produce bicarbonate and subsequently monocarbonate of soda; the limestone used for producing the carbonic acid would yield the lime required for absorbing the chlorine, and produce bleaching powder instead of being run into the rivers in combination with chlorine in the useless form of chloride of calcium; and both the ammonia (used as an intermediary in the production of soda), and the metallic oxide (used as an intermediary in the production of chlorine), would be continuously recovered.

The realisation of this fascinating problem has occupied me for a great many years. In the laboratory I obtained soon almost theoretical results. A very large number of oxides and even of salts of weak acids were found to decompose ammonium chloride in the desired way; but the best results (as was to be clearly anticipated from thermo-chemical data) were given by oxide of nickel.

When, however, I came to carry this process out on a large

scale, I met with the most formidable difficulties, which it took many years to overcome successfully.

The very fact that ammonium chloride vapour forms so readily metallic chlorides when brought in contact at an elevated temperature with metals or oxides or even silicates, led to the greatest difficulty, viz. that of constructing apparatus which would not be readily destroyed by it.

Amongst the metals we found that platinum and gold were the only ones not attacked at all. Antimony was but little attacked, and nickel resisted very well if not exposed to too high a temperature, so that it could be, and is being, used for such parts of the plant as are not directly exposed to heat. The other parts of the apparatus coming in contact with the ammonium chloride vapour I ultimately succeeded in constructing of cast and wrought iron, lined with fire-bricks or Doulton tiles, the joints between these being made by means of a cement consisting of sulphate of baryta and waterglass.

After means had been devised for preventing the breaking of the joints through the unequal expansion of the iron and the earthenware, the plant so constructed has lasted very well.

Oxide of nickel, which had proved the most suitable material for the process in the laboratory, gave equally good chemical results on the large scale, but occasionally a small quantity of nickel chloride was volatilised through local over-heating, which, however, was sufficient to gradually make up the chlorine conduits. We therefore looked out for an active material free from this objection. Theoretical considerations indicated magnesia as the next best substance, but it was found that the magnesium chloride formed was not anhydrous, but retained a certain amount of the steam formed by the reaction, which gave rise to the formation of a considerable quantity of hydrochloric acid on treatment with hot air. In conjunction with Dr. Eschellman (who carried out the experiments for me), I succeeded in reducing the quantity of this hydrochloric acid to a negligible amount by adding to the magnesia a certain amount of chloride of potassium, which probably has the effect of forming an anhydrous double chloride.

This mixture of magnesia and potassium chloride is, after the addition of a certain quantity of china clay, made into small pills in order to give a free and regular passage throughout their entire mass to the hot air and other gases with which they have to be treated. In order to avoid as far as possible the handling and consequent breaking of these pills, I vapourise the ammonium chloride in a special apparatus, and take the vapours through these pills and subsequently pass hot air through, and then again ammonium chloride vapour, and so on, without the pills changing their place.

The vapourisation of the ammonium chloride is carried out in long cast-iron retorts lined with thin Doulton tiles, and placed almost vertically in a furnace which is kept by producer gas at a very steady and regular temperature. These retorts are kept nearly full with ammonium chloride, so as to have as much active heating surface as possible. From time to time a charge of ammonium chloride is introduced through a hopper at the top of these retorts, which is closed by a nickel plug. The ammonium chloride used is very pure, being crystallised out from its solution as produced in the ammonia soda manufacture by a process patented by Mr. Gustav Jarmay, which consists in lowering the temperature of these solutions considerably below 0° C. by means of refrigerating machinery. The retorts will, therefore, evaporate a very large amount of ammonium chloride before it becomes necessary to take out through a door at their bottom the non-volatile impurities which accumulate in them. The ammonium chloride vapour is taken from these retorts by cast-iron pipes lined with tiles and placed in a brick channel, in which they are kept hot, to prevent the solidification of the vapour, to large upright wrought-iron cylinders which are lined with a considerable thickness of fire-bricks, and are filled with the magnesia pills, which are, from the previous operations, left at a temperature of about 300° C. On its passage through the pills the chlorine in the vapours is completely retained by them, the ammonia and water vapour formed pass on and are taken to a suitable condensing apparatus. The reaction of the ammonium chloride vapour upon magnesia being exo-thermic, the temperature of the pills rises during this operation, and no addition of heat is necessary to complete it. The temperature, however, does not rise sufficiently to satisfactorily complete the second operation, viz. the liberation of the chlorine and the re-conversion of the magnesium chloride into magnesium oxide by means of air. This reaction is slightly endo-thermic, and thus absorbs a small amount of heat, which has to be provided in one way or another. I effect this by heating the pills to a somewhat higher temperature than is required for the action of the air upon them, viz. to 600 C., by passing through them a current of a dry inert gas free from oxygen heated by a Siemens-Cowper stove to the required temperature. I use for this purpose the gas leaving the carbonating plant of the ammonia soda process.

This current of gas also carries out of the apparatus the small amount of ammonia which was left in between the pills. It is washed to absorb this ammonia, and after washing, this same gas is passed again through the Siemens-Cowper stove, and thus constantly circulated through the apparatus, taking up the heat from the stove and transferring it to the pills. When these have attained the required temperature, the hot inert gas is stopped and a current of hot air passed through, which has also been heated to 600° C. in a similar stove. The air acts rapidly upon the magnesium chloride, and leaves the apparatus charged with 18 to 20 per cent. of chlorine and a small amount of hydrochloric acid. The chlorine comes gradually down, and when it has reached about 3 per cent. the temperature of the air entering the apparatus is lowered to 350° C. by the admixture of cold air to the hot air from the stove; and the weak chlorine leaving the apparatus is passed through a second stove, in which its temperature is raised again to 600° C., and passed into another cylinder full of pills which are just ready to receive the hot-air current. A series of four cylinders is required to procure the necessary continuity for the process.

The chlorine gas is washed with a strong solution of chloride of calcium, which completely retains all the hydrochloric acid, and is then absorbed in an apparatus invented by Dr. Carl Langer, by hydrate of lime, which is made to pass by a series of interlocked transporting twin-screws in an opposite direction to the current of gas, and produces very good and strong bleaching powder, in spite of the varying strength of the chlorine gas. The hydrochloric acid absorbed by the solution of calcium chloride can by heating this solution be readily driven out and collected.

This process has now been in operation on a considerable scale at our Works at Winnington for several years, with constantly improving results, notably with regard to the loss of ammonia, which has gradually been reduced to a small amount. The process has fully attained my object, viz. to enable the ammonia soda process to compete, not only in the production of carbonate of soda, but also in the production of bleaching powder, with the Le Blanc process.

Nevertheless, I have hesitated to extend this process as rapidly as I should otherwise have done, because very shortly after I had overcome all its difficulties, entirely different methods from those hitherto employed for the manufacture of chlorine were actively pushed forward in different parts of the globe, for which great advantages were claimed, but the real importance and capabilities of which were and are up to this date very difficult to judge. I refer to the processes for producing chlorine by electrolysis.

During the first decade of this century, Humphry Davy had by innumerable experiments established all the leading facts concerning the decomposing action of an electric current upon chemical compounds. Amongst these he was the first to discover that solutions of alkaline chlorides, when submitted to the action of a current, yield chlorine. His successor at the Royal Institution, Michael Faraday, worked out and proved the fundamental law of electrolysis, known to everybody as "Faraday's Law," which has enabled us to calculate exactly the amount of current required to produce by electrolysis any definite quantity of chlorine. Naturally, since these two eminent men had so clearly shown the way, numerous inventors have endeavoured to work out processes based on these principles for the production of chlorine on a manufacturing scale, but only during the last few years have these met with any measure of success.

It has taken all this time for the classical work of Faraday on electro-magnetism to develop into the modern magneto-electric machine, capable of producing electricity in sufficient quantity to make it available for chemical operations on a large scale; for you must keep in mind that an electric installation sufficient to light a large town will only produce a very moderate quantity of chemicals.

In applying electricity to the production of chlorine, various ways have been followed, both as to the raw materials and as to the apparatus employed. While most inventors have proposed

to electrolyse a solution of chloride of sodium, and to produce thereby chlorine and caustic soda, I am not aware that up to this day any quantity of caustic soda made by electrolysis has been put on to the market.

Only two electrolytic works producing chlorine on a really large scale are in operation to-day. Both electrolyse chloride of potassium, producing as a bye-product caustic potash, which is of very much higher value than caustic soda, and of which a larger quantity is obtained for the same amount of current expended. These works are situated in the neighbourhood of Stassfurt, the important centre of the chloride of potassium manufacture. The details of the plant they employ are kept secret, but it is known that they use cells with porous diaphragms of special construction, for which great durability is claimed. There are at this moment a considerable number of smaller works in existence, or in course of erection in various countries, intended to carry into practice the production of chlorine by electrolysis by numerous methods, differing mainly in the details of the cells to be used; but some of them also involving what may be called new principles. The most interesting of these are the processes in which mercury is used alternately as kathode and anode, and salt as electrolyte. They aim at obtaining in the first instance chlorine and an amalgam of sodium, and subsequently converting the latter into caustic soda by contact with water, which certainly has the advantage of producing a very pure solution of caustic soda. Mr. Hamilton Castner has carried out this idea most successfully by a very beautiful decomposing cell, which is divided into various compartments, and so arranged that by slightly rocking the cell the mercury charged with sodium in one compartment passes into another, where it gives up the sodium to water, and then returns to the first compartment, to be recharged with sodium. His process has been at work on a small scale for some time at Oldbury near Birmingham, and works for carrying it out on a large scale are now being erected on the banks of the Mersey, and also in Germany and America.

Entirely different from the foregoing, but still belonging to our subject, are methods which propose to electrolyse the chlorides of heavy metals (zinc, lead, copper, &c.) obtained in metallurgical operations or specially prepared for the purpose, among which the processes of Dr. Carl Hoepfner deserve special attention. They eliminate from the electrolyte immediately both the products of electrolysis, chlorine on one side and zinc and copper on the other, and thus avoid all secondary reactions, which have been the great difficulty in the electrolysis of alkaline chlorides.

All these processes have, however, still to stand the test of time before a final opinion can be arrived at as to the effect they will have upon the manufacture of chlorine, the history of which we have been following, and this must be my excuse for not going into further details. I have endeavoured to give you a brief history of the past of the manufacture of chlorine, but I will to-day not attempt to deal with its future! Yet I cannot leave my subject without stating the remarkable fact that every one of these processes which I have described to you is still at work to this day, even those of Scheele and Berthollet, all finding a sphere of usefulness under the widely varying conditions under which the manufacture of chlorine is carried on in different parts of the world.

Let me express a hope that a hundred years hence the same will be said of the processes now emerging and the processes still to spring out of the inventor's mind. Rapid and varied as has been the development of this manufacture, I cannot suppose that its progress is near its end, and that nature has revealed to us all her secrets as to how to procure chlorine with the least expenditure of trouble and energy. I do not believe that industrial chemistry will in future be diverted from this Section and have to wander to Section A under the ægis of applied electricity. I do not believe that the easiest way of effecting chemical changes will ultimately be found in transforming heat and chemical affinity into electricity, tearing up chemical compounds by this powerful medium, and then to recombine their constituents in such form as we may require them. I am sure there is plenty of scope for the manufacturing chemist to solve the problems before him by purely chemical means, of some of which we may as little dream to-day as a few years ago it could have been imagined that nickel would be extracted from its ores by means of carbon-monoxide.

At a meeting of this Association which brings before us an entirely new form of energy, the Röntgen rays, which have enabled us to see through doors and walls and to look inside the human body; which brings before us a new form of matter, represented by Argon and Helium, which, as their discoverers, Lord Rayleigh and Prof. Ramsay, have now abundantly proved, are certainly elementary bodies, inasmuch as they cannot be split up further, but are not chemical elements, as they possess no chemical affinity and do not enter into combinations—at a meeting at which such astounding and unexpected secrets of nature are revealed to us, who would call in doubt that, notwithstanding the immense progress pure and applied science have made during this century, new and greater and farther-reaching discoveries are still in store for ages to come?

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE action of the nominating Committee of the American Association (see NATURE of September 10), in recommending a merely formal meeting next year at Toronto, on the day preceding that of the British Association, evoked a storm of opposition in the general session, and a vote was passed requiring the Council to arrange for a regular meeting and fix the time and place.

The Council subsequently fixed on August 9, 1897, as the time, and Detroit as the place, providing for a recess to Toronto before the final adjournment, in order to welcome the British Association.

Of the various Sections, popular interest evidently centred in that of Social and Economic Science, as was evinced by the very large attendance, and by the attention devoted to its proceedings by the daily press of Buffalo. The first paper read before this section, on "The Monetary Standard," taking strong ground for the gold standard, was read by Wm. H. Hale. Edward Atkinson sent a paper entitled "What is True Money?"; also one entitled "Crime against Labour." Other papers were: "The Competition of the Sexes and its Results," by Lawrence Irwell; "Fashion—a Study," by S. E. Warren; "Citizenship, its Privileges and Duties," "Relics of Ancient Barbarism," and "Practical Studies in Horticulture, Art and Music," by S. F. Kneeland; "An Inheritance for the Waifs," by C. F. Taylor; "The Proposed Sociological Institution," by James A. Skilton; "The Value of Social Settlement," and "The Wages Fund Theory," by A. B. Keeler; "Better Distribution of Forecasts," by John A. Miller; "The Tin-plate Experiment," by A. P. Winston, and "Suicide Legislation," by W. L. O'Neill.

Thirty-five papers were read in the Anthropological Section, including contributions from Brinton, Boas, McGee, Fletcher, Beauchamp, Wright, Mercer, and others. Especial interest was felt in the paper of Secretary F. W. Putnam, on the researches made in the ancient city of Coapan, located in Honduras, just over the border from Guatemala.

Prof. Putnam was the first to go beneath the surface. He began in Yucatan, and soon found that buildings now on the surface were of recent date; but underneath were indications of remote antiquity. City has been built over city, in one place as many as five having been superposed, showing as many successive occupations.

The two Biological Sections had twenty-three papers in zoology and forty-two in botany. Among the well known contributors were L. O. Howard, E. D. Cope, L. M. Underwood, T. N. Gill, D. S. Kellicott, C. E. Bessey, J. M. Coulton, and N. L. Britton, The Botanical Club also held several meetings, and the botanists devoted all day Friday to an excursion by lake to Point Abino.

The Geological Section was enriched by all the papers from the Geological Society of America, which held merely a business meeting, an arrangement now adopted for the first time, but so successfully that it will be extended next year to the Chemical Society, and ultimately to other affiliated societies. Thirty-four papers were read to the geologists, among prominent contributors being B. K. Emerson, Warren Upham, I. C. White, E. W. Claypole, G. K. Gilbert, and J. W. Spencer. H. O. Hovey, who has made a speciality of cave explorations, gave interesting accounts of new discoveries in Mammoth Cave and elsewhere. The feature of this Section was the commemorative exercises on Wednesday afternoon, referring to the sixtieth anniversary of the work of Prof. James Hall in connection with the survey of New York State. Addresses and papers were given by Prof. Emerson, Prof. Joseph Le Conte, W. J. McGee,

John M. Clarke, and others. Three of those present at that gathering had attended the meeting of the American Association for the Advancement of Science at Albany in 1856, at which Prof. Hall presided, and which was the largest scientific gathering up to that time held in America. They were Joseph Le Conte, Thomas H. Feary, and Wm. H. Hale.

The proximity of Niagara, and the new applications of power, gave special interest to the Section of Mechanical Science and Engineering, and twenty-two papers were read. Henry T. Eddy, Thomas Gray, J. E. Denton, D. S. Jacobus, and Octave Chanute were among the contributors. A most important paper was read by Elmer L. Corthell, entitled "Some Notes, Physical and Commercial, upon the Delta of the Mississippi River." Mr. Corthell has made a special study of the Mississippi for many years. He points out certain measures where he pronounces necessary to preserve navigation of the delta. The United States has already expended thirty-eight million dollars in the improvement of the Mississippi.

The Chemical Section was crowded with papers, about seventy being read. Among the contributors were A. A. Noyes, A. B. Prescott, H. W. Wiley, R. B. Warder, F. W. Clarke, T. H. Norton, C. B. Dudley, W. P. Mason, J. L. Howe, C. F. Mabery, H. A. Weber, E. W. Hilyard, A R. Leeds, Wm. McMurtrie, L. L. Van Slyke, and E. A. de Schweinitz. The papers were mostly technical, and were arranged in groups according to the subjects. The programme of the American Chemical Society, which met in the preceding week, was also a long one, indicating an unusual interest in chemistry. At the meeting Prof. Dennis stated that he had found potassium platinocyanide, $K_2Pt(CN)_4$, by far the best material for painting fluorescent screens for X-ray investigation.

Physics also aroused much interest, and it was remarked that the Section had never had a better programme. Of the thirty-two papers presented, Wm. A. Rogers read five. In one of these he maintained that X-ray pictures could be obtained by the use of static electricity, and he exhibited several pictures taken in that manner. Among others, papers were read by Ernest Merritt, Edward L. Nichols, and Alexander Macfarlane.

The Section of Mathematics and Astronomy was the lightest of all, having only ten papers and no presidential address, Mr. Wm. E. Story being absent in consequence of sickness in his family. Alexander Macfarlane was elected vice-president in his place. G. W. Hough contributed a paper on motion of the great red spot and equatorial belt of the planet Jupiter from 1879 to 1896, and L. A. Bauer one on component fields of the earth's magnetism.

The evening addresses before the Association were by J. W. Spencer, on "Niagara as a time-piece," and by E. D. Cope, on "The results of cave explorations in the United States, and their bearing on the antiquity of man." Spencer's last estimate of the age of Niagara is 31,500 years. In about 5000 years he predicts that the elevation of the north-east will suffice to turn the drainage of the great lakes into the Mississippi River. Prof. Cope gave an exhaustive review of cave explorations.

Contributions to the monument to Pasteur were solicited from the Association, but funds were not available, except from Mrs. Esther Herrman, a patron of the Association, who contributed 100 dollars for that purpose. Grants for research were only made to the extent of 200 dollars, for the same reason ; and were allocated as follows :—To the Marine Biological Laboratory, Woods Holl, Mass., for a table (appointment to be made by the vice-presidents for Sections F and G and the director of the laboratory), 100 dollars; to Francis E. Phillips, for investigations on the properties of natural gas, 50 dollars ; to L. A. Bauer for investigations on terrestrial magnetism in connection with the magnetic survey of Maryland, 50 dollars.

The President and Vice-Presidents of the next meeting are :— President, Wolcott Gibbs. Vice-Presidents : (A) Mathematics and Astronomy, W. W. Beman ; (B) Physics, Carl Barus ; (C) Chemistry, W. P. Mason ; (D) Mechanical Science and Engineering, John Galbraith ; (E) Geology and Geography, I. C. White ; (F) Zoology, G. Brown Goode ; (G) Botany, George F. Atkinson ; (H) Anthropology, W. J. McGee ; (I) Social and Economic Science, Richard T. Colburn.

An unusually large number of Fellows were elected, among whom must be mentioned Wolcott Gibbs, he having been elected honorary fellow in order to qualify for the presidency of the Association, of which he had not been a member for nearly thirty years.

The matter of the approaching jubilee (in 1898) of the Association was discussed, but no definite decision was arrived at. As the probable place of meeting that year, Secretary Putnam suggested Boston, a city already memorable in the annals of the Association as the place where the largest meeting of members—not counting foreign guests—was held.

THE RECENT CYCLONE IN PARIS.

THERE seems to be very little doubt that Paris on Thursday last was visited by a tornado, the first time within the memory of man. It was accompanied by that mysterious circular motion that is special to this class of storm, and extended over a very small area, beginning at the Place St. Sulpice and ending at the Boulevard de la Villette, a distance of nearly two miles. It, however, caused considerable damage, resulting in, it is said, seven deaths and many severe injuries. On the day in question there had been since noon a succession of showers, and it was towards the last of these—about 3 p.m.—that the tornado showed itself. M. Angot, head of the Meteorological Bureau, was at the Pont Royal, about to take a boat, when he noticed small dark clouds, very low down, apparently moving against the wind, which was not at all high, the velocity not being more than five or six yards a second. He soon, however, perceived that the clouds had a rapid circular motion, not horizontal, but oblique. When making these observations he judged the distance of the storm to be about a mile, and its diameter about 170 yards. At the Tour St. Jacques, the meteorologist there states that the storm lasted less than a minute. Some black clouds passed swiftly overhead, and there was one flash of lightning. The barometer suddenly fell from 748 mm. to 742 mm., a drop of 6 mm. ; a fact unprecedented for years, but almost immediately afterwards rose again. Advancing from this point towards the north-east, branches and, in some cases, whole trees fell on the roadways, and boats on the river were torn from their moorings and dashed on the quays. Omnibuses were upset, cabs thrown about, and stalls overturned. So strong was the force of the wind that the Palais de Justice had its windows broken and was partly unroofed. The roofs of the Opéra Comique, the Châtelet, the Tribunal of Commerce, and the Préfecture of Police were considerably damaged, and in some cases partly removed. Owing to the great damage done to the numerous windows of every house, the streets were strewn with enormous quantities of glass broken into small pieces. Some curious instances are related. A kiosk in front of the Ambigu, in which were seated two policemen, was carried, together with the policemen, to the other side of the street ; the kiosk was completely wrecked, but the policemen were unhurt though shaken. The heavy rain which continued during the storm did considerable damage, filling up cellars, &c., and flooding the river Bièvre. It was owing, perhaps, to this rain, which had cleared the streets of people, that the number of accidents was not greater than was recorded.

We have received the following further details from a correspondent in Paris :—

"The storm which we experienced took meteorologists quite by surprise, and it was found impossible to follow the track of the cyclone out of Paris. It appears that it developed at the Place St. Sulpice, and disappeared at La Villette, seven kilometres in the north-north-east direction.

"The path of destruction was limited to about one hundred yards, but omnibuses were overturned, boats on the Seine wrecked, five persons killed, seventy wounded, and about 100 trees uprooted. One of the most extraordinary places of devastation was the Square de la Tour Saint Jacques, where the Central Municipal Observatory is established. The branches of trees accumulated by the wind were so numerous that I was obliged to use ladders for visiting the observers, who were practically prisoners in the observatory. Most interesting observations were taken from the top of the Eiffel Tower ; these will be discussed in the forthcoming International Congress of Meteorology."

In a later communication our correspondent says :—

"A singular observation was registered on the barometer at 2h. 40m. p.m. on the 10th, when the storm raged in Paris. A rise of 1 mm. of mercury was registered, but of such a short duration that it was hardly possible to detect the two separate strokes for the greater part of the variation. (It may here be

stated that the instrument was a self-recording one, the mode of registration being graphical.) A similar aërial commotion was registered at the Tour St. Jacques; but, instead of marking an increase of pressure, the trace showed a depression of 6 mm., and of very short duration."

PREHISTORIC EUROPEAN ART.

IT is important to determine how far culture can independently arise in a given district, and how far it is dependent upon other centres of civilisation. For many years M. Salomon Reinach has devoted himself to these problems, especially in reference to the culture of prehistoric Europe. In his essays on "Le Mirage Orientale" he opposed the very prevalent idea that all our culture necessarily came from the East, and during the last three years he has contributed to *L'Anthropologie* a series of articles on "Sculpture in Europe before the Greco-Roman Influences." This long series of papers is concluded in the current number (No. 2, vol. vii.) of that journal, and it forms a mine of information which cannot but prove of immense value to archæological students, especially as it is illustrated with 441 outline sketches culled from a vast array of authors. His general thesis comprises two arguments—the one negative, the other positive.

(1) M. Reinach tries to prove that the most primitive European artistic remains are far from justifying the view that the first models and tentative efforts came from Egypt or Babylon. One cannot trace any imitation of Assyrian cylinders or of Egyptian funereal figurines. The fauna figured by the rude artists of Europe is purely European; there is no lion, panther, or camel. An apparently very grave difficulty occurs in the series of figures representing nude females, which authors agree in regarding as imitations of the Babylonian Astarte. M. Reinach argues that this type was indigenous, and so far from owing its existence to Babylonian influence, it, on the contrary, worked its way, in all probability, towards the valleys of the Euphrates and Tigris. He thinks that Europe (*i.e.* the Balkan Peninsula, the Archipelago, the Caucasus, and the west coast of Asia Minor) only later, and to a restricted degree, became dependent upon the old civilisations of the Orient. In his opinion culture is polygamist. He admits multiple centres of creation for art, and refuses to believe that all illumination has come to us from the Euphrates and the Nile. He thinks that the Danube and the Rhine have some rights which should not be neglected, and that the future barbarians who dwelt along the borders of these rivers were not reduced to receive everything from without.

(2) M. Reinach recognises that it is not sufficient to affirm that art can be born in diverse places, and that the germ has not arisen from two or three privileged centres of the ancient world; and so he sets himself to show how the rudiment of art has been able to arise, even among peoples whose genius was for a long time in abeyance. To that purpose M. Reinach has "insisted on the evolution of the most simple decorative motives which, at a certain point, quite naturally suggested the idea of the human or animal form. In these not very numerous cases one can follow the transformations of a plastic motive down to the entirely geometric figure from which it arose. But the taste for geometric forms and the tendency to conventionalisation (*stylisation*), that is to say, to the purely decorative modification of organic lines, have been, for long centuries, so powerful in Europe, that even foreign types have not escaped their petrifying action. *A fortiori*, the indigenous types, arisen from geometrical devices, have always been constrained to return back to them again. It is not denied that in Europe, as elsewhere, the imitation of surrounding nature has given origin to some plastic attempts; but there is proof that this inspiration drawn from nature has been feeble, even in the imitation of animal forms, which represented only a very small number of the animals known to the people."

The author admits that several statuettes figured in this memoir reflect outside influences, particularly of Italy, where Ionian art early took root. But these influences were not exercised in an immediate manner, and the indigenous style appears to have always been predominant even when brought face to face with foreign objects. A similar phenomenon is noticeable in Italy itself, which was Hellenised very slowly, and was only partially Orientalised under the Roman empire.

Such is an outline of M. Reinach's position. There is no doubt that it will open up a wide discussion, as he covers a great deal of ground, and deals with some matters which admit of diversity of opinion.

M. Reinach, in an earlier section of his memoir (*L'Anth.* v., 1894, p. 305), definitely states that "in the primitive art of Central Europe the geometric form (a triangle) has suggested the anthropomorphic form, and it is not the anthropomorphic figure which is degenerated into the geometric." Possibly some, at all events, of these flat plates had indications of features painted on their surface, and thus they may have been more realistic than now appears, and later they were made more human-like as the fabricators became more skilled, or as they valued greater realism.

The investigations of quite a number of men of science show that so-called "geometric" designs are often really highly conventionalised representations of natural objects, mainly of animals; others are suggestions of textiles, or other handicrafts. Probably relatively few "geometric" designs are purely meaningless decorations. So far as available evidence goes, there are not many (if any) examples of the evolution of human or animal forms by "suggestion" from purely geometric designs, but the reverse process is extremely common. Doubtless some of the problems involved in this memoir will be fully discussed at the forthcoming meeting of the British Association at Liverpool during the great discussion, which has been arranged for on the culture and origins of the Mediterranean race. We understand that M. Reinach intends to be present on this occasion, when he will be able to state his views and reply to his critics.

NOTES.

THE seventh annual general meeting of the Federated Institution of Mining Engineers began, with a good attendance, at Cardiff on Tuesday last, under the presidency of Mr. G. A. Mitchell. The report of the Council showed satisfactory progress. It was announced that Mr. Lindsay Wood has been elected President of the Institution.

THE third annual congress of Sunday Societies is announced to take place at Newcastle-on-Tyne, on October 10 and two following days. Copies of the programme of proceedings may be had of the Honorary Secretary, Mr. Mark H. Judge, 7 Pall Mall, S.W.

A REUTER dispatch from Naples says the death is announced of Senator Palmieri, Director of the Vesuvius Observatory. Luigi Palmieri was born in 1807. He was successively Professor of Mathematics at Salerno, Campobasso, and Avellino, Professor of Physics at the Royal Naval School at Naples, and Professor at the University in the same town. In 1854 he was appointed Director of the Vesuvius Meteorological Observatory. He was inventor of several instruments for the observation of natural phenomena, including an electrometer for ascertaining the amount of electricity in the atmosphere, a rain gauge, and a seismometer.

PROF. J. C. BOSE, of the Presidency College, Calcutta, is at present in this country, having been deputed by the Indian Government to visit the various laboratories in Great Britain and on the continent, with a view to the extension of the Calcutta Presidency College Laboratory, and the establishment of a new magnetic observatory in connection with that College. Prof. Bose is the holder of a Royal Society grant for researches in regard to electricity. He is a D.Sc. of London University.

IT was announced at a banquet given to Dr. Nansen at Christiania, on Thursday last, that a Nansen fund had been formed for the advancement of science. Subscriptions to the amount of 210,000 kroners had already been received.

THE Russian Geographical Society has been asked by the Governor-General of Turkestan to send some men of science to Shignan and Roshan next summer, for the purpose of making a thorough exploration of those regions.

M. MOUREAUX, who has just returned from Russia, has made observations of some quite surprising magnetical perturbations. On August 29, special perturbations were observed by him of the same kind that are generally registered when connected with earthquakes. He remained several days supposing that he had been mistaken, when he learned through a steamer which arrived that Hecla had been in eruption on that same night. The exact times of occurrence of these perturbations were 11h. 36m., 11h. 42m., 11h. 46m. p.m. Paris mean time.

PROF. H. MOHN informs us that Captain Salvesen, Royal Norwegian Navy, commanding the sloop-of-war *Ellida*, on July 28, when off the promontory of Stat, on the west coast of Norway, saw the "blue sun" at sunset. The phenomenon was seen twice, the ship being lifted on the waves, with an interval of a few seconds of time. The sun was quite clear at setting. It is curious that this beautiful sight is so rarely looked for.

IT is reported that the War Department of the United States has sent to Paris for a set of the Bertillon instruments, and that a thorough examination into the system of identification is to be made with a view to its introduction into the United States Army.

THE *Evening Post* of New York learns that Prof. C. W. Dodge, of the Biological Department of the University of Rochester, has asked the trustees to make an appropriation for the establishment of a biological laboratory at Hemlock Lake, a small lake thirty miles south of Rochester, from which the city obtains its water-supply. Prof. Dodge proposes to make, with the assistance of students from his department, a complete biological survey of the lake.

PROF. A. HALL, JUN., Director of the University of Michigan Observatory, according to *Popular Astronomy*, has secured an extensive series of observations of Polaris for latitude variation. He is also engaged on the division errors of the meridian circle, no examination of the errors having been made for some considerable time.

MR. E. H. PARKER, who has been for the past fifteen years in the experimental department of Messrs. Wm. Denny and Bros., Leven Ship-yards, has been appointed Secretary to the Institution of Engineers and Shipbuilders in Scotland, in the place of Mr. W. D. Millar, who is retiring after twenty-five years' service.

WE have received from Colonel A. T. Fraser, R.E. (retired list), two radiographs, one of a European, and the other of a Hindu hand, taken by means of Röntgen rays under precisely similar conditions. Colonel Fraser is of opinion that the evident difference in appearance suggests that the skin pigment of the hand of the Hindu intercepts the rays.

THE Society of Medical Phonographers, to which we have referred on former occasions, has made steady progress during the past year, and now has 250 names on its books. The Society issues a monthly medical periodical, entitled the *Record*, in lithographed shorthand; in addition to this publication it has brought out two small pamphlets dealing with the use of shorthand by the student and by the practitioner respectively, and has issued a list of more than 2500 phonographic outlines of medical terms. The Society intends, at the end of October or the beginning of November, to hold an examination in shorthand for students of medicine commencing their first winter session. Prizes will be given for proficiency in the art.

A LIST of free popular lectures to be delivered in the Chemical Theatre of Owens College, Manchester, on Saturday afternoons during the session, has been sent us. On October 24 will be begun the first of three discourses on "The Geological History of the District round Manchester," by Prof. Boyd Dawkins, and on subsequent dates the following lectures will be given:—"The Inhabitants of the Seas," by Prof. Hickson; "Economic Botany," by Prof. Weiss; "Soils, their Nature and Origin," by Dr. Burghardt; "Birds," by Mr. Hoyle. In addition to these lectures, others of a popular character will be delivered on Monday evenings during the session. In the list we notice one by the Archdeacon of Manchester, on "Falling Stars as a Branch of Astronomy"; one on "The Electric Furnace," by Prof. Roberts-Austen; and two, by Prof. H. B. Dixon, on "The Nature of Flame."

THE *Pioneer Mail* (Allahabad) of August 19 contains an account of the proceedings at the last meeting of the Central Committee of the Pasteur Institute of India. At this meeting it was unanimously decided "that the scope of the Institute as embodied in the extended scheme laid before the meeting be accepted and published." The scheme in question is as follows: I. The practical application of bacteriological methods to the prevention and cure of disease, viz.: (*a*) Inoculations against rabies. (*b*) Preparation and preservation of cholera vaccines for distribution when necessary, and the carrying out of anti-cholera inoculations. (*c*) Preparation of diphtheria anti-toxin. (*d*) Preparation of anthrax vaccine. (*e*) Preparation of tuberculin (for diagnostic purposes). (*f*) Preparation of mallein (for diagnostic purposes). (*g*) Vaccination against tetanus. II. The investigation of tropical diseases especially prevalent in India; that is to say: (*a*) Research intended to generalise methods already in use, and to test the actual value of proposed methods, namely: (1) Vaccination against enteric fever. (2) The use of *anti-venene* in snake-bit. (3) The curative treatment of cholera. (*b*) The investigation of the following diseases: malaria, kala azar, dysentery, abscess of the liver, beri beri, &c. (*c*) Fermentations, including indigo, opium, tea. III. The provision of a centre which would afford to medical officers, already trained in bacteriological technique, the means for the prosecution of independent research, and for the acquisition of advanced knowledge of bacteriological methods of dealing with disease, under the guidance and supervision of the officers of the Institute. The selection of the site for the Institute has yet to be made.

WE are glad to hear that the Crystal Palace Company are about to arrange for a series of entertainments and lectures during the ensuing autumn and winter months, to be given every Wednesday evening. The lectures will be devoted to the exemplification of the various great discoveries and inventions of the Victorian era, and will be delivered by eminent men of science. We wish the Crystal Palace every success in this venture, and hope that the Company's example may be followed by others. The last half-century, perhaps, holds the record for the greatest advancement in science during a period of this length, so that the lectures will have a broad basis from which to draw their material.

VERY little doubt now exists as to the value of a captive balloon for reconnoitring purposes; and its importance has been lately displayed during the recent manœuvres. The military correspondent of the *Pall Mall Gazette* gives an interesting account of this special detachment; it consists of three officers and a dozen sappers. The balloon can lift $2\frac{1}{2}$ cwt. The apparatus consists of a cart drawn by four horses, with two drums or winches, and round them is the hawser of twisted strands of wire which anchors the balloon. The balloon is generally allowed to ascend 1000 feet, and this is done by unwinding the wire. Messages are sent down in small bags fixed loosely on the hawser, and the officer at the bottom is either connected by wire with the General's headquarters, or has mounted orderlies at his disposal. A simple and rapid

means is adopted for bringing the balloon to earth. A stout pole, 10 feet long, is laid on the wire, and a couple of sappers take hold of each side, and double along, pressing on the pole all the time. The balloon is then made to come to earth in about two minutes; of course, some distance from the waggon. To let it up again, they double back, keeping the pole of the waggon horizontal; this system naturally saves much time and winding. To move the balloon from place to place, it is pulled down until it is on the top of the waggon, where it is held while the waggon is being driven along. The value of a balloon, the correspondent says, can hardly be over-estimated, both for reconnoitring the enemy and also as a means of keeping a General informed of the positions reached by his own troops. Sketches showing accurately all the enemy's dispositions can be thus easily obtained, which would otherwise have to be done by mounted troops, and, perhaps, not so thoroughly.

Considerable danger appears to attend the consumption of the popular Norwegian cheese known as "Pult-ost" or "Knad-ost," in consequence of the vigorous kneading which it undergoes in process of manufacture. Several authentic instances of severe attacks of intestinal catarrh having followed the eating of this particular variety of cheese, attention has at last been directed to the subject, and an elaborate investigation has lately been carried out by Dr. Axel Holst. of Christiania. The bacteriology of the cheese in question has been specially studied, and elaborate examinations were made of those cheeses to which the above epidemic was attributed. The results obtained are of considerable interest; for not only has Dr. Holst isolated out the responsible microbe, but he has identified it as being a virulent variety of the *B. coli communis*. Thus fresh evidence is to hand in support of the now frequently expressed view that this microbe, so extensively present in our surroundings, and normally present in the animal system as a harmlesss saprophyte, may by some process, at present unknown to us, become endowed with highly toxic properties. Dr. Holst suggests that the original infection of the milk may have been brought about by want of cleanliness in milking, coupled with an unhealthy condition of the cow itself—circumstances which have already been proved to have induced diarrhœa in the case of persons who consumed such contaminated milk.

Dr. C. Hart Merriam, of the U.S. Department of Agriculture, has prepared a synopsis of the weasels of North America, which has just been issued from the Government printing office. Dr. Merriam recognises one ferret and twenty-two weasels, as being at present known in North America, and refers the former to the sub-genus *Putorius*, and the latter to the sub-genus *Ictis* of the same genus. Eleven species of North American weasels are now described as new for the first time. Five plates are added to this excellent memoir to illustrate the skulls and dentition of the various species.

From a memoir lately presented to the Imperial Academy of Sciences of St. Petersburg by Herr Eug. Büchner, it would appear that the European bison, in spite of the stringent efforts made by the Czars since the beginning of the present century for its protection, is likely to share the fate of its American relative, and to become extinct as a wild animal. The celebrated herd of the forest of Bjelowjesha, in Lithuania, which in 1856 was nearly 1900 in number, has of late years become reduced to under 500, and shows no signs of increase. The chief cause of this failing is attributed, by Herr Büchner, to "breeding in," in consequence of the confined area to which these huge animals are now restricted. Another reason is, no doubt, the fact that the male bisons considerably exceed the females in number. We venture to suggest that it would be wise to remove a large number of bisons of the male sex from the forest, and, if possible, to introduce a change of blood from the second herd of the same animal which still exists on the northern slopes of the Caucasus.

A very interesting feature of primary education in Russia is the establishment and rapid development of small farms, orchards, and kitchen-gardens in connection with many primary schools, especially in the villages. The land for such model gardens, or farms on a small scale, was mostly obtained through free grants from the village communes and, occasionally, from the neighbouring landlords; while the expenses are covered by very small money grants from the country and district Councils (*zemstvos*). To take one province in South Russia, namely Ekaterinoslav, we see from the biennial report, just issued, that not only has almost every school an orchard and kitchen-garden for the use of the schoolmaster, but that nearly one-half of the schools in the province (227 out of 504) are already in possession of small model kitchen-gardens, orchards, tree-plantations, or farms, at which gardening, sylviculture, and sericulture are regularly taught. The teaching is mostly given by the schoolmasters, who themselves receive instruction in these respective branches at courses voluntarily attended in the summer, or occasionally by some practical specialist of the neighbourhood. The province of Ekaterinoslav being mostly treeless, special attention is given to tree plantations and, next, to silkworm culture. The aggregate area of the 227 school-farms or gardens attains 283 acres, and they contained, in 1895, 111,000 fruit trees and 238,300 planted forest trees; nearly 14,000 of the former and 42,000 of the latter having been distributed free among the pupils during the same year. The money grants for these 227 gardens were very small—*i.e.* a little over three hundred pounds (£314). Besides, over a thousand beehives are kept, partly by the schoolmasters and partly by the children; and some schools had vineyards in connection with them. This movement has widely spread over different provinces of Central Russia, where the culture of cereals dominates at the school farms; while in Caucasia attention is especially given to the silkworm culture and the culture of the vine.

The following particulars of munificent gifts and bequests to libraries of America are gathered from *Science*:—The New York Free Library, from members of the Astor family, about £330,000; from James Lennox, £147,000, in addition to books and land; from the Tilden estate, £400,000; the John Crerar Library, of Chicago, from the founder, about £540,000; the Newberry Library, of Chicago, from the founder, about £500,000; the Carnegie Library, of Pittsburg, from the founder, £420,000; the Enoch Pratt Free Library, of Baltimore, from the founder, about £216,000; the Library Company, of Philadelphia, from the founder, Dr. Rush, about £212,000; the Library of Columbia University, from President Low, £200,000.

The first article in the September part of the *Geological Magazine* is devoted to an historical account of the Palæontographical Society of London, the jubilee of which was celebrated on June 19 last. The origin of the Society was mainly due to the prior issue of Sowerby's "Mineral Conchology," of which the first part appeared in June 1812, and was followed by other parts for over thirty years. The portions of this work were brought out slowly and irregularly, and rarely illustrated more than ten species at one time, and it was thought that as the "Mineral Conchology," at its then rate of issue, could not possibly depict all the British fossils within a moderate period, it would be well to have recourse to another method. The outcome of the suggestion made was the calling together of a meeting on March 23, 1847, at the apartments of the Geological Society, with Sir Henry De la Beche in the chair, when it was resolved that a Society be constituted, the object of which should be "to figure and describe as completely as possible a stratigraphical series of British fossils." The meeting

further determined that the annual subscription should be one guinea, that the name of the Society should be the Palæontographical, and that its officers should consist of a president, treasurer, secretary, and council of sixteen members. Sir Henry De la Beche was elected first president. The presidents from the foundation to the present have been: Sir H. De la Beche, from 1847 to 1855; Mr. W. J. Hamilton, from 1856 to 1867; Dr. Bowerbank, from 1868 to 1876; Sir R. Owen, from 1877 to 1892; Prof. Huxley, from 1893 to 1895; and since then Dr. Henry Woodward. Want of space will not permit of our giving a list of the monographs issued by the Society; suffice it to say that they range over a large area of information comprehending the fossil Plantæ, &c., fossils from the sub-kingdoms Protozoa, Porifera, Cœlenterata, Echinodermata, Annulosa, Mollusca, and Vertebrata; and that monographs are in progress on the Foraminifera of the Crag, the Fossil Sponges, the Cretaceous Star-Fishes, the Carboniferous Mollusca, the Inferior Oolite Ammonites, the Fishes of the Old Red Sandstone, the Pleistocene Mammalia, and the Devonian Fauna. The Honorary Secretary of the Society, Prof. Wiltshire, will, we are sure, be glad to receive the names and subscriptions of many new members.

IT may be remembered that some time ago the Austrian man-of-war *Pola* returned from her voyage of investigation in the Red Sea, after having spent eight months there, and surveyed the northern half of this region, covering an area of about 600 nautical miles long by 180 broad. An account of the work accomplished during this trip is given in *Die Natur* (No. 37), and seems to be of great importance. No less than seventy boxes, containing fish and smaller Seetiere, and twelve large boxes full of coral have already been despatched to Vienna. Other results of observation tell us that at a depth of 500 metres the water commences to become homogeneously warm, having a temperature to the bottom of 21°·2. The amount of salt at the time of observation was greatest in the northern part, diminishing towards the south; the transparency of the water was found to be less than that of the Mediterranean Sea; and the colour was not so fine and of such a distinct blue as is the case of the Mediterranean and Adriatic Seas. Altogether 1243 temperature observations, 691 determinations of the specific gravity at the surface, half-way down, and at the bottom, 254 colour observations, and 22 determinations of wave-elements were made. The investigation included further innumerable chemical analyses of the water from the deeper parts, and observations of the chemical changes taking place between the Red Sea and the land surfaces. At most of the harbours and places of anchorage the officers made astronomical position and time determinations, magnetic observations for all three elements—declination, inclination, and intensity, and pendulum observations for the determination of the force of gravity. The above were made at twenty-seven stations on land and islands, twelve being on the Egyptian coast, ten on the Arabian, and the rest on the half-island Sinai. Meteorological observations were also strictly made, thus completing a valuable amount of work in an important region.

THE current number of *La Nature* (September 12) has some specially interesting articles. M. de Navaillac gives us an account of some of the prehistoric finds that have been made in Florida, referring to the work done especially by Mr. Frank Cushing, who was sent out by the University of Pennsylvania. His researches seem to have been very successful, and he was rewarded with sufficient material to permit him to describe the life and costumes of the race that had peopled the land. Dr. Felix Regnault discourses on the origin of ornamental art: the principles which actually guide ornamental art date neither from the Renaissance, nor even from the Greek period. They result "d'une tendance naturelle à l'homme telle qu'on retrouve dans les origines mêmes de l'humanité." "Renaissance Clocks" is the subject of an article by M. Planchon, who describes some of these beautiful works of art. There are several illustrations showing the different methods of design adopted.

THE *Bulletin de la Société d'Encouragement pour l'industrie Nationale* for the month of August contains various articles which should be read with interest. M. Ronna, in a long summary of sixty-four pages, gives an account of the dry regions in the United States of America, and describes at some length the different methods of irrigation employed to suit the various local conditions. Plans, cross-sections and photogravures are given to illustrate the regions under discussion, and these give us a good idea of the enormous scale on which some of the undertakings are made. The first part deals chiefly with the distribution of water, by the formation of reservoirs, and the subsequent building of canals. The question of wind and steam pumps then passes under review; here all kinds of types are mentioned, including an account of some of the more important artesian wells. Then follows the different systems adopted for actually distributing the water over areas, such as, for instance, a plantation; these vary according to the amount of water required. The statistics brought together show the enormous increase in the productive value of the land since the adoption of irrigation on a large scale. Under the heading of "Metallurgy," Roberts-Austen's and F. Osmond's researches on the structure of metals are translated.

IN the current number of the *Annales de Chim. et de Phys.*, M. Moissan gives an interesting account of his experiments on the volatilisation of refractory substances in the electric furnace. The sublimates were condensed on the outside of a curved copper tube placed two centimetres below the arc, and just above the substance under examination. A rapid current of water was passed through the tube, and kept it cool during the experiments, which usually lasted for about five minutes. The volatilised metals were copper, silver, platinum, aluminium, tin, gold, manganese, iron, and uranium. Quantitative experiments were not made in every case, but it appeared that manganese was sublimed more rapidly than the others, and that the rate of volatilisation of copper was about five times as rapid as that of gold. The condensed metal was usually, in great part, in the form of little spheres. Silicon and carbon were also volatilsed and condensed on the tube, though the amount collected of the last-named element was very small, and lime, magnesia, zirconia and silica were sublimed without difficulty. M. Moissan draws the conclusion that the most stable compounds hitherto known disappear in the electric furnace, being either decomposed or volatilised. Nothing resists these high temperatures except the series of perfectly crystallised compounds discovered by him, and consisting of borides, silicides, and, above all, carbides of the metals. M. Moissan intends to publish a description of these compounds shortly. He regards them as being probably among the original constituents of the globe, and as still existing in some of the stars.

THE earliest recorded measurements of the "dip" of the earth's magnetism were made in London by Robert Norman in the year 1576, and by Gilbert in 1600; but it was not until 1671 that this element formed the subject of a series of regular observations at Paris, indicating a continual diminution during the last two centuries from 75° to 65° 5′. In endeavouring to trace the secular variation of the dip, it is important to obtain, if possible, data extending over a far longer period. In a highly suggestive paper published in the *Atti dei Lincei*, Dr. G. Folgheraiter, taking as his starting-point the well-known property possessed by clay after it has been baked of retaining permanently any magnetisation that may have been induced in

it during the process of baking, advances the view that the various objects of terra-cotta discovered in excavations (vases, bricks, &c.) afford an indelible record of the state of the earth's magnetism at the epoch of their fabrication. The author, besides citing the observations of a number of physicists in support of his view, has put the matter to a practical test by examining the magnetisation of the bricks used in the construction of ancient villas, tombs, &c., at the time of the Roman Empire, of which the remains abound in Rome and the Campagna. It was found that the direction of magnetisation varied from brick to brick, some in the course of building having been laid with their axes of magnetisation in the opposite direction to the earth's magnetic force, some with their axes in the same direction, while others were magnetised normally to that direction; in no case did the axis of magnetisation correspond to any fixed direction, thus proving that the bricks had retained their polarity unaffected by terrestrial magnetism during the many centuries that have elapsed since the buildings were constructed. An examination of some Etruscan vases, dating from the eighth century B.C., leads to similar conclusions. In a tomb recently discovered at Narce (now Calcata), one of two vases was found magnetised in a nearly horizontal direction, the other exhibited a decided south pole at the bottom, and a north pole at the top, while two large *crateræ* had their north poles in the centre of the base, and their south poles in the orifice at the top. In a tomb at Falerii, two vases were found having the south pole in the centre of the base, while one "oinochoë" (wine measure), accompanying them, had the north pole at the upper extremity of its beak. From such evidence Dr. Folgheraiter considers himself justified in asserting with certainty that the direction of magnetisation observed in antique objects of terra-cotta is that due to the inducing effect of the earth's magnetism during the process of baking. In this, his first paper, the author draws no inferences relating to the earth's magnetism, but he points out a difficulty arises in most instances, owing to our uncertainty as to the orientation of the objects when originally placed in the kiln, a factor which must evidently be known before any definite conclusions can be stated.

THE August number of the *Proceedings* of the Geologists' Association contains a paper by Dr. Hicks on the Palæozoic Rocks of West Somerset and North Devon, in which are some original illustrations of the remarkable folds in the rocks of the Ilfracombe district. This is followed by a preliminary Synopsis of the Fauna of the Pickwell Down, Baggy, and Pilton Beds, by the Rev. G. F. Whidborne, in which brief descriptions of some seventy-four new species are included. The Rev. H. H. Winwood contributes notes on the Trias, Rhætic and Lias of West Somerset. These three papers have already been issued as the usual Long Excursion pamphlet. In addition the number contains a paper by Mr. A. E. Salter on the "Pebbly Gravel" of South-east England, and the relation of its distribution to the gaps in the present line of high-ground between Goring and the Norfolk coast; and one, by Mr. Strahan, on the physical geology of Purbeck and the relations of the anticlines to the watersheds in the south and south-east of England.

THE recent number of the *Proceedings* of the Liverpool Geological Society (vol. vii., part iv., dated 1896 only) contains an important presidential address by Mr. Mellard Reade, on British Geology in relation to Earth-Folding and Faulting; while a contribution to the same subject, in respect of the Craven district, is made by the Rev. F. F. Grensted. Among other papers of more than local interest we may mention Mr. Beasley's Attempt to classify the Footprints from the Trias of the district: Mr. Mellard Reade's Notes on the Drift of Mid-Wales; Mr. Lomas's Observations on Recent Glacial Striæ in Switzerland; and Dr. Callaway's Sketch of the Process of Metamorphism in the Malvern Crystallines.

Science for September 4 contains a lengthy appreciative article on Dr. P. L. Sclater, F.R.S., from the pen of Dr. G. Brown Goode.

THE Annual Report of the Keeper of the Manchester Museum has reached us, and is of a very encouraging character. During the year the Museum was recognised in a practical manner by the City Council as a public institution, for on October 16, 1895, a resolution was passed at a meeting of the Council that the sum of £400 a year should be granted to the Manchester Museum from the Free Library Rate. In November the experiment of opening the Museum for two hours on Sunday afternoons was first made. On the opening day, November 17, 494 persons attended. Since that date the attendance has varied from 131 to 797, the average being 519. During the year the Museum has received a large number of gifts from individuals and institutions.

VOL. XXVIII. of the *Transactions and Proceedings of the New Zealand Institute* (published in this country by Messrs. Kegan Paul and Co., Ltd.) is a bulky volume of 787 pages, and contains seventy-four articles classified as miscellaneous, or relating to zoology, botany, geology, and chemistry. In addition to these, reports of the proceedings of the incorporated societies are given, and the whole is enriched by thirty-seven well-executed plates.

THE Annual Report of the Calcutta Botanic Gardens, issued by the Superintendent, Dr. G. King, shows steady work and increase in efficiency in the various departments, notwithstanding the severe injury inflicted by the unusual drought of the summer months (October to March). The work of the herbarium has been carried on with vigour, a very large number of specimens have been added to it, while named specimens of Indian plants have been forwarded to various scientific institutions throughout the world.

THE *Botanical Gazette* records the establishment of a Biological Survey by the Department of Agriculture, under a recent Act of Congress of the United States, which it regards as the beginning of a new era in the botanical field-work of the States. The head of the new Survey will be Dr. Merriam, who has had great experience in the kind of work which it proposes to undertake.

THE corner-stones of the Hull Biological Laboratory of the University of Chicago were laid in July last. The Botanical Hall is expected to be finished by the spring of 1897, and, if we may judge from a sketch in the *Botanical Gazette*, will be a very imposing structure.

VOL. VI. part ii. of "Flora Capensis: being a Systematic Description of the Plants of the Cape Colony, Caffraria, and Port Natal (and neighbouring territories)," by various botanists, and edited by Mr. W. T. Thiselton-Dyer, is almost ready for publication by Messrs. L. Reeve and Co. Like part 1 of vol. vi., the present contribution is the work of Mr. J. G. Baker, the keeper of the Herbarium and Library of the Royal Gardens, Kew, and contains the continuation of the *Amaryllideæ* and part of the *Liliaceæ*, to the completion of which the whole of the third and concluding part will be devoted.

MESSRS. RIVINGTON, PERCIVAL, AND CO. will publish shortly, "Mechanics for Beginners treated Experimentally, embracing Statics, Dynamics and Hydrostatics," by L. Cumming, of Rugby School.

MESSRS. HENRY HOLT AND CO., New York, hope to issue at an early date a translation, by Prof. G. W. Field, of Brown University, of the first or "general" part of Dr. Hertwig's "Lehrbuch der Zoologie."

A NEW edition of Dr. Oliver Lodge's "Elementary Mechanics, including Hydrostatics and Pneumatics" has just reached us from Messrs. W. and R. Chambers, Ltd. It has been completely revised by the author and by Prof. Alfred Lodge.

MESSRS. TAYLOR BROTHERS, Leeds, have sent us the second edition of "The Collector's Manual of British Land and Freshwater Shells," by L. E. Adams. The preface states that the book has been re-written and brought up to date.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*, ♂ ♀) from India, presented respectively by Mr. John Hart and Mr. E. E. Hodgskins; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. Frederick Tomlin; a Mozambique (*Cercopithecus pygerythrus*, ♂) from South-east Africa, presented by Mr. A. C. Jackson; two Lanner Falcons (*Falco lanarius*), South European, presented by Mr. W. Glynes Bruty; a Glaucous Gull (*Larus glaucus*) from Franz Josef Land, presented by the Jackson-Harmsworth Polar Expedition; a Raven (*Corvus corax*), British, presented by Mr. O. L. Pegler; an Egyptian Jerboa (*Dipus ægyptius*) from North Africa, a Rat-tailed Serpent (*Trigonocephalus lanceolatus*) from St. Lucia, W.I., deposited; a Diana Monkey (*Cercopithecus diana*, ♀) from West Africa, three Capeira Partridges (*Odontophorus dentatus*) from Brazil, purchased; a Red Deer (*Cervus elaphus*, ♀) from Scotland, received in exchange; two Triangular-spotted Pigeons (*Columba guinea*), a White-backed Pigeon (*Columba leuconota*), two Half-collared Doves (*Turtur semitorquatus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE RECENT SOLAR ECLIPSE.—M. Tisserand furnishes a few details on the results obtained by the Russian astronomers during the eclipse of August last, which were communicated to him through M. Backlund, Director of the Observatory of Pulkowa. M. Backlund's station was situated in Novaya Zemlya, where he landed three weeks before the day of the eclipse. During this period the sky remained constantly cloudy, the temperature varying from 0° to 3° C. During some occasionally bright moments altitudes of the sun were obtained to check their chronometers and determine their rates. M. Galitzine made a series of magnetic observations. At four o'clock on the morning of the eclipse the sky was still overcast, but the weather cleared up somewhat, and the observers were able to observe the four contacts under good conditions. Clouds, however, were not entirely absent; but successful observations and photographs of the corona were taken.

M. Eugène-M. Antoniadi, in the September number of the *Bulletin de la Société Astronomique de France*, gives an account of his trip in the *Norse King* to Vädso. The article in question is illustrated, and contains, among others, a drawing of the region in and about Vadsö, and an excellent photogravure of the town of Hammerfest.

COMET BROOKS.—A Centralstelle Circular, dated September 10, gives an ephemeris, with elements, of this comet computed by Prof. E. Lamp from observations made on September 7, 8, and 9. They are as follows:—

Elements.

$$T = 1896 \text{ July } 7{\cdot}278 \text{ Berlin M.T.}$$
$$\left.\begin{aligned} \omega &= 38^\circ\ 22' \\ \Omega &= 149^\circ\ 22' \\ i &= 88^\circ\ 16' \end{aligned}\right\} 1896{\cdot}0$$
$$\log q = 0{\cdot}06497.$$

Ephemeris 12h. Berlin M.T.

1896.	α h. m.	δ ° ′	log Δ	B.
Sept. 16	14 55·9	+53 15	0·2405	0·9
20	15 21·0	51 53	0·2428	0·8
24	15 44·7	50 16	0·2463	0·8
28	16 6·9	48 26	0·2512	0·7
Oct. 2	16 27·6	46 29	0·2574	0·7
6	16 46·7	44 25	0·2650	0·6

The unit of brightness occurred on September 4.

COMET GIACOBINI.—A circular from Kiel, dated September 9, gives the elements and ephemeris of this comet calculated by Dr. H. Kreutz from observations on September 5, 6, and 7.

Elements.

$$T = 1896 \text{ October } 8{\cdot}003 \text{ Berlin M.T.}$$
$$\left.\begin{aligned} \omega &= 155^\circ\ 2'{\cdot}1 \\ \Omega &= 195^\circ\ 39'{\cdot}5 \\ i &= 8^\circ\ 45'{\cdot}2 \end{aligned}\right\} 1896{\cdot}0$$
$$\log q = 0{\cdot}04004$$

These elements are stated to be somewhat uncertain. The orbit is probably an ellipse.

Ephemeris 12h. Berlin M.T.

NEW FEATURE ON MARS.—With reference to the recent observation of bright light on the terminator of Mars, referred to on September 3, we may state that the bright prominences (mountains?) on the terminator of Mars were first seen by the astronomers of the Lick Observatory in 1890, and have been regularly observed (measured) at subsequent oppositions by the observers at Mount Hamilton, Nice, and Flagstaff.

Prof. Hussey observed their first appearance in 1896 on August 28, 0h. 45m. Greenwich mean time, in the *Chersonesus* region of Mars.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

IT is announced that a sum of between £15,000 and £17,000 is to be spent in providing buildings and fixtures for the Sunderland Technical College.

AMONG recent appointments we notice the following:—Mr. Lake becomes Principal of the Technical and University Extension College, Colchester; and Mr. J. W. B. Adams, Head-master of the Tenby and Intermediate and Technical Schools.

MR. A. M. DRENNAN, of the Burnley Grammar School, has been appointed Head-master of the Banbury Municipal Secondary and Technical School.

AMONG recent appointments abroad may be mentioned:—Prof. W. Dames to succeed the late Prof. Beyrich in the chair of Geology and Palæontology at Berlin; and Dr. W. Wien, to be Associate Professor of Physics at Berlin.

THE Chemical Laboratory of the University of Illinois has been destroyed by fire. It is reported to have been one of the largest and best-appointed of its kind in the country, and was erected at a cost of about £8000. Its fittings, apparatus, &c., are said to have added to this amount about £7000.

THE Syllabus of the Municipal Technical School and Municipal School of Art, Manchester, for the forthcoming session is now ready. It is issued by Mr. John Heywood, Manchester. The Calendar for the twelfth session of the Merchant Venturers' Technical College, Bristol, is also ready, and may be had, at a small charge, of Mr. H. Y. Hill, Bristol. We have also had sent to us the prospectus of day and evening classes to be conducted at the Battersea Polytechnic Institute. Copies may be obtained on application to the Secretary.

THE fifth annual report of the Department of Agriculture of the Yorkshire College, Leeds, is a record betokening much activity. Most of the lecture courses appear to have been well attended, though in the teachers' agricultural classes the attendance fell off so considerably that it was found impossible to hold a summer vacation course. In the winter courses the same difficulty was experienced, and though attempts were made to form classes at five centres, it was only possible to obtain sufficient students to form one class. At the request of the West Riding County Council, the department formulated a scheme for the institution of gardens for instruction in horticulture in connection with evening continuation schools. The scheme has been adopted by the West Riding County Council, and grants have been promised by them provided certain regulations are complied with.

SCIENTIFIC SERIAL.

American Journal of Science, September.—On the regular or specular reflection of the Rontgen rays from polished metallic surfaces, by O. N. Rood. Platinum foil at an angle of incidence of 45° reflects $\frac{1}{200}$th part of the incident X-rays. About half the rays are reflected in a regular geometrical or specular manner, as proved by photographs of iron gratings obtained by means of the reflected rays, and compared with photographs obtained with the same mirrors by means of ordinary light, diffused or radiating from a point. But the proportion of regularly reflected rays is less than in the case of ordinary light. There is a greater proportion of diffused rays, but these are diffused, not as they would be by a dull surface, but as they would be by an imperfectly polished surface. Similar results were obtained with speculum metal and tinfoil.—An iodometric method for the determination of phosphorus in iron, by Charlotte Fairbanks. Phosphorus may be determined in iron by precipitating the ammonium phospho-molybdate according to the usual methods of iron analysis; then reducing the phospho-molybdate thus obtained with potassium iodide and hydrochloric acid; neutralising the residue with acid sodium carbonate, and reoxidising with standard iodine.—Is the land round Hudson Bay at present rising? by J. B. Tyrrell. The reasons advanced by Dr. Robert Bell for supposing that the land round Hudson Bay is still rising are not conclusive. The land at the mouth of the Churchill River has been unchanged for the last century and a half. Sloops Cove, where the sloops engaged on the Eskimo trade used to winter, has many inscriptions of the middle of the eighteenth century, whose position, when compared with their exact date, shows that they would not have been hewn into the rock at the level they occupy if the tides had at that time attained a higher level than they do now.—A visit to the Great Barrier Reef of Australia, by A. Agassiz. The expedition, supported by the United States, the British, and the Queensland Governments, was equipped for extensive pelagic fishing and topographical surveying inside and outside the Barrier Reef. Boisterous weather made pelagic fishing very difficult, and the explorers had to content themselves with an examination of the inner portions. The slope is greatest in the southern portion, where the channel is wider. There is evidence to show that the islands composing the reef formerly filled up the channel as well. The islands lining the continent were the last to disappear. The very moderate subsidence which has taken place in comparatively recent times cannot have shaped the outlines of the present Australian continent, and of its submarine extension. For this we must look back, first to the subsidence which took place in Cretaceous times, next to the subsequent elevation of the Cretaceous beds, and finally to the erosion and denudation to which these beds, since their elevation above the level of the sea, have for so long a period been subjected. It is on the upper part of these submarine slopes, dating back to an earlier geological period, but modified by erosion and denudation up to recent times, that during the present epoch corals have obtained a footing and built up the Great Barrier Reef of Australia.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 7.—M. A. Cornu in the chair.—Notice on the late Amé-Henry Resal, by M. Maurice Levy.—On the observations of the eclipse of the sun of August 9 last. Extract from a letter to M. Tisserand by M. Backlund, Director of the Observatory of Pulkowa. Athough for some time preceding the eclipse the weather had been extremely unfavourable, the first contact was observed in a perfectly clear sky, and a dozen good photographs were obtained.—Memoir on the thermo-chemistry of the oxygen compounds of phosphorus, arsenic and sulphur, by M. Marcellin Langlois.—On the steering of aërostats, by M. Rozier.—On the employment of a fixed circle, derived from any group of seven tangents to a conic, to define, *à priori*, the circle derived from any seven right lines, by M. Paul Serret.—On the distribution of deformations in metals submitted to stresses, by M. L. Hartmann. A reply to some remarks by M. Charpy.—Discharge of electrified bodies by the X-rays, by M. E. Villari. The experiments described tend to show that the discharge of electrified bodies is not brought about by the X-rays themselves, but by the air rendered active by their passage.—On the emission of the X-rays, by M. C. E. Guillaume. A theoretical proof of the laws of emission established experimentally by MM. Imbert and Bertin-Sans, and by M. Gouy.—On the general relation between the intensity of sensation and the duration of a luminous impression, by M. Charles Henry.—On some questions in celestial mechanics, by M. A. Karagiamides.—On nervo-psychosis, by M. Bouxteieff.

SYDNEY.

Royal Society of New South Wales, June 3.—Mr. J. H. Maiden, President, in the chair.—The following papers were read:—On periodicity of good and bad seasons, by Mr. H. C. Russell, C.M.G., F.R.S.—The Mika operation of the Australian Aborigines, by Prof. Anderson Stuart.—The absorption of water by the gluten of different wheats, by Mr. F. B. Guthrie.

July 1.—Mr. J. H. Maiden, President, in the chair.—Discussion upon the paper read by Mr. Russell at the preceding meeting.—Notes on recent developments of Röntgen rays, by Prof. Threlfall.

August 5.—Mr. J. H. Maiden, President, in the chair.—Papers read:—On the occurrence of a submerged forest with remains of the dugong at Shea's Creek, by Mr. R. Etheridge, jun., Prof. T. W. E. David, and Mr. J. W. Grimshaw (with exhibits).—On aromadendrin or aromadendric acid from the turbid group of *Eucalyptus kinos*, by Mr. Henry G. Smith.—On the cellular kite, by Mr. Lawrence Hargrave (with exhibit).—Note on a method of separating colloids from crystalloids by filtration (with demonstration); also an explanation of the marked difference in the effects produced by subcutaneous and intravenous injection of the venom of Australian snakes, by Dr. C. J. Martin.—Mr. H. G. Smith exhibited a specimen of Lapidolite (*Lithia mica*) from near Norseman, West Australia.

BABYLONIAN MAGIC AND SORCERY.

Babylonian Magic and Sorcery. By L. W. King, M.A. Pp. xxx + 199. (London: Luzac and Co., 1896.)

IT is clear from the seventy-five plates of cuneiform texts with which Mr. King has furnished his book, that he addresses himself mainly to the little group of cuneiform scholars who in England, America, and Germany are pushing on their science with strenuous endeavours; but those who take the trouble to read his translations of these texts, and his remarks upon the same, will at once see that he is in reality speaking to a much larger audience—namely, to all those who take an interest in the science of the ancient religions of the world, and to those who spend their time in tracing the development of the sister subjects of magic and sorcery from the earliest ages to the present day. The foundation of all real study in comparative religion must, after all, be the documents which the priests wrote, and the copies of them which the scribes attached to the temples made for their use; no student of anthropology can afford to neglect the evidence obtained from these sources, and the student of comparative religion who ignores them imperils both his credibility and reputation. Further, all schemes of the religions of ancient nations which are drawn up without due consideration of every available document must be defective, and are, probably, useless, and no man should theorise without his sheaf of facts, that is to say his ancient texts, at his elbow. It is now some sixty years since Rawlinson and Lassen found the key which unlocked our storehouse of native Babylonian and Assyrian information on this subject; and yet until within the last five years we possessed very little exact information concerning the religious beliefs of the Babylonians and of the people of the more northerly country of Assyria. We had translations of hymns and of documents which were clearly of a religious nature, but they afforded us no real insight into the system of religion which existed in Mesopotamia in the earliest times; moreover, both texts and translations were generally fragmentary and disconnected, and in cases where they were not so the reader was puzzled, and could not guess their true significance. Little by little, however, as students devoted themselves to the subject, it was found that the text on a tablet was not necessarily complete in itself, and soon it was recognised that many tablets were needed for copying a religious work, or, as we might say, "service." Next it was found that certain parts of the texts consisted of rubrical directions, and then it was known that we had become the fortunate possessors of copies of the "service-books" which were probably in use in Babylonia several thousands of years before Christ. Most of these copies were made by the order of the great King Assur-bani-pal (Asnapper), for use in his Royal Library at Nineveh in the seventh century B.C.; and, as a large number of words, names, and phrases in them were in the agglutinative language of the non-Semitic peoples of Mesopotamia, it was pretty clear that the king had had these compositions translated from it into his own Semitic speech. We now know that the ancient peoples of Mesopotamia possessed a series of legends concerning the Creation of the heavens and of the earth and of all that is therein; a series of legends of the deeds of the mythical hero Gilgamish; and a series of mythological stories. They had formed in their imagination an abode for the gods, and an underworld wherein the souls of the dead had their place together with the infernal gods. They had, at an early date, formulated a great trinity of Anu, Ea and Bel, and they gave to one of their gods, at least, the attribute of mediator and intercessor between men and their god. They believed in the efficacy of prayer when accompanied by certain ceremonies, and in brief they held many religious ideas and beliefs in common with their cousins the Hebrews. Whether they ever succeeded in establishing a personal relation with their god or gods, is open to doubt; but the texts which Mr. King has published lead us to think that a development in this direction was going on when the Assyrian Empire was overthrown. The group of compositions which Mr. King has edited belongs to a class of texts which are known to scholars as the "Prayers of the Lifting of the Hand," and all of them were written for the use of individuals, the name of the suppliant at times being given. Many prayers to be efficacious must be accompanied by an offering of some object to the god, and it was necessary that the rubrical directions should be strictly adhered to; certain prayers were, however, only potent at certain times—as, for example, on a lucky day, or at night, or during a certain phase of the moon. It is probable, too, that, as in ancient Egypt, the correct recital of a prayer was deemed of the first importance, and that any prayer offered without the burning of incense was in vain. The use of fire in the accompanying ceremonies was common and of the utmost importance, and its purifying properties were well understood; and as the flame consumed the object which the suppliant, or the priest on his behalf, cast into it, so the disease, or calamity, or trouble vanished straightway. The part played by fire in certain religious ceremonies was so prominent that two series of inscribed Assyrian tablets were called *Shurpu* and *Maklū* respectively; both these names mean "burning." As a specimen of a petition, we quote the following lines from an address to Ishtar:—

> "Have mercy on me, O Ishtar! Command abundance.
> "Truly pity me and take away my sighing. . . .
> "I have borne thy yoke: do thou give consolation. . . .
> "I have sought thy light: let thy brightness shine.
> "I have turned towards thy power: let there be life and peace. . . .
> "Speak, and let the word be heard.
> "Let the word I speak, when I speak, be propitious.
> "Let health of body and joy of heart be my daily portion.
> "My days prolong, life bestow: let me live, let me be perfect, let me behold thy divinity.
> "When I plan, let me attain (my purpose): Heaven be thy joy, may the Abyss hail thee."

When these words had been said an offering of incense and a drink-offering were set before Ishtar, and the suppliant raised his hand three times.

Our space will not admit of further quotation from this interesting work, and we have only to add, for the in-

formation of the general reader, that it should be studied in connection with the recent works of Tallqvist and Zimmern on the *Maklû* and *Shurpu* series of tablets in the British Museum. A word of praise is justly due to Mr. King for his honest work, and although the introduction might have been fuller with advantage to the reader, the translations, and transliterations, and vocabulary will help to make the texts at the end of the book understood by every careful reader.

MICRO-ORGANISMS AND DISEASE.

Micro-organisms and Disease; an Introduction to the Study of Specific Micro-organisms. By Dr. E. Klein, F.R.S. New edition. Pp. xii + 595. (London: Macmillan & Co., Ltd., 1896.)

THE rapid strides which have been made in bacteriological science during the last few years render the frequent revision of the text-books on the subject a necessity. It is a noteworthy fact that although bacteriology is one of the newest of the sciences, it is rapidly becoming so large a subject that specialisation in one branch or other of it is almost essential.

Dr. Klein's book treats mainly of that particular branch of bacteriology which deals with "pathogenic" micro-organisms, including only a very small number out of the total known species. Other branches of bacteriology have also their specialised handbooks—*e.g.* the micro-organisms in water are sufficiently numerous and well-known to require a text-book to themselves, whilst it would be easy to mention other branches of the subject which will soon require similar treatment. In this new (third) edition of Dr. Klein's work we find the subject brought practically up to date. The present edition is enlarged to 595 pages, as against 267 pages in the previous one. There are 80 additional illustrations, as compared with the last edition, making 201 in all. Amongst them are inserted, for the first time, a number of well-reproduced photographs of cultures and of excellent stained preparations of bacteria, taken by the well-known photomicrographers Messrs. Pringle and Bousfield. These are almost uniformly good, but photographs, such as Fig. 63A, mar an otherwise fine series.

The introductory chapters deal with bacteriological technique, such as the preparation of culture media, stained microscopic preparations, methods of inoculation and cultivation, bacteriological examination of water, air and soil. Then follows a full discussion of the general characters of bacteria—more especially of the pathogenic organisms—in which their mode of growth, spore formation, means of motility, &c., are discussed.

The chapter on "The Chemistry of Bacteria," confined as it is to a dozen pages, merely serves to show how meagre is the bacteriologist's knowledge of this part of the subject. It is a chapter, however, which might easily be amplified with advantage. For example, in writing on the liquefaction of gelatine, no mention is made of the fact that such liquefaction is due to an enzyme, and that it can be brought about by the agency of sterile filtered cultures of liquefying bacteria, apart from the bacteria themselves. Similarly, no reference is made to other enzymes, such, for instance, as those which bring about the hydrolysis of starch, &c.

A brief glance at the succeeding chapters will show how extensive is the list of diseases which are associated with specific micro-organisms. To mention only a few of the best known, we find considered in this book—often very exhaustively—typhoid, cholera, tuberculosis, tetanus, diphtheria, influenza, erysipelas, pneumonia, gonorrhœa, anthrax, glanders, relapsing fever, fowl cholera, grouse disease, Oriental plague, &c.

In the concluding chapters we find an epitome of the latest results of the labours of many workers in the field of serum therapeutics, a subject which is just now attracting so much attention from medical men and bacteriologists, and the experimental results of which are of the most far-reaching importance. The newest methods of research are clearly set forth, and the results obtained by recent workers are fully discussed.

Dr. Klein's views on the proper interpretation of the results of researches in various branches of his subject are frequently at variance with those of other authorities, yet it is refreshing to find—in these days of the premature publication of incomplete work—an author who is ready to stand out for a logical proof of the correctness of conclusions which are often drawn from meagre and incomplete evidence. There is no one in this country whose views on various controversial matters, coming within the scope of the book, are more entitled to careful consideration than are those of Dr. Klein.

The latest methods of protective inoculation by antitoxic blood serum, more particularly in diphtheria and tetanus, are noticed and discussed. In this connection one regrets that more space is not devoted to the closely related subject of snake-poison and its antidote. The methods pursued are so similar, and the results already achieved are so important, that the subject might easily be brought within the scope of the book, especially as such diseases as cancer are included, although a disease which is most probably not associated with micro-organisms.

Under the heading of "Protozoa causing disease" is found a valuable discussion of the vexed question of the parasitic or non-parasitic nature of cancer. Dr. Klein shows very clearly the kind of fallacy into which the "parasitologists" and discoverers of "cancer organisms" have easily fallen.

Bacteriology has, during the last few years, become more and more complex. Where a single organism was previously recognised, it is now becoming certain that there are very many modifications and sub-varieties of each, which can only be differentiated and distinguished from each other by difficult methods. Nowhere is this more obvious than in reading the chapters containing descriptions of *Bacillus coli communis* and of the typhoid and cholera organisms.

The book is beautifully printed, and, with a few exceptions, the illustrations merit great praise.

There seem to be very few misprints. On p. 89, however, a reference is made to the work of Downes and Lunt; this should, of course, be Downes and Blunt. Also, on pp. 588 and 595, Vehring is inserted for Behring.

The author is to be congratulated on the completion of this revised and much enlarged edition of his valuable book, which ought to be in the hands of every medical man.

JOSEPH LUNT.

OUR BOOK SHELF.

Text-book of Zoology. By Dr. J. E. V. Boas. Translated by J. W. Kirkaldy and E. C. Pollard. Pp. xviii + 558; with 427 figures. (London: Sampson Low, Marston, and Co., Ltd., 1896.)

THE "Text-book of Zoology," by Dr. Boas, which is now presented to English students in this country in the form of a translation by Miss Kirkaldy and Miss Pollard, has this advantage over many similar books at present in use, that it is complete in one volume. The translators have done their work well in keeping closely to the German text, and in forming clear and concise English sentences made up of English words. Regarded simply as a translation of a German book, it is far better than most of its predecessors, and the translators may be congratulated upon their share of the work. But the book is not one which English teachers will be able to recommend to the "beginners in the study of zoology" who attend their classes, notwithstanding many excellent features which may be found in several chapters. It would be difficult for them to heartily recommend to their students, as a guide to their studies, a book which classifies Limulus with the Entomostraca, and Peripatus with the Annelida; nor can they consider it to be complete, even for elementary work, in the absence of any account of such important forms as Balanoglossus, Rhabdopleura and Phoronis.

Apart from these blemishes of primary importance, there are many others which detract very considerably from its value as a text-book for students. The description of Amphioxus, for example, is so short, and the figures so poor and inaccurate, that no beginner could possibly recognise the importance and interest of the group to which it belongs. The same may be said of the group Tunicata, which is described in four pages at the end of the Vertebrata, and illustrated by only four very poor figures.

The book, moreover, is disfigured by many strange blunders and inaccuracies, of which a few may be given. The rich animal fauna of the deep sea does *not* "resemble the cave fauna." Alcyonium is *never* dimorphic; there is *no* chitinous perisarc in Millepora, which is calcified; *Hirudo medicinalis* is *not* indigenous in England. Nor is the book thoroughly up to date in many particulars. The account given of the gills of Lamellibranchiata might have been written fifteen years ago. The results of Leche's important work upon the succession of mammalian teeth are not even briefly mentioned. Nor can the account of the epidermal structures of Vertebrata be said to be complete when no reference is made to Prof. Weber's extremely important observations on the scales of Manis.

It is possible, however, that some teachers in this country may find the book useful for occasional reference. Some of the diagrammatic figures are new and fairly accurate. The introductory chapters on cells and tissues and on embryology are excellent, and some of the chapters on vertebrate animals are better than in any modern text-book of zoology with which we are acquainted.

The Antichrist Legend: a Chapter in Christian and Jewish Folk-lore. Englished from the German of W. Bousset, with a Prologue on the Babylonian Dragon Myth. By A. H. Keane. Crown 8vo. Pp. xxxi + 307. (London: Hutchinson and Co., 1896.)

AT various intervals certain well-meaning individuals, with enthusiasm inversely proportional to their knowledge, attempt expositions of such extremely difficult texts as the Books of Daniel and Revelation, and they glibly profess to explain the Antichrist, and are impressive on the Beast. They little realise that, as Bousset says, "to understand Revelation we need a fulness of eschatological and mythological knowledge." One has only to glance through Bousset's erudite work to be convinced that it is only by the most patient and learned research that such problems can be solved, and so we welcome Mr. Keane's translation of this valuable study, and hope (probably in vain) that the latter-day prophets will cease to yield to the temptation of giving free play to their fancy, and will investigate the historical growth of legendary beings, and thus eventually become students of folk-lore. It is evident, from the researches of Bousset and Gunkel, that Belial, the Antichrist, and the numerous other variants of Christian and pre-Christian authors, are adaptations of the ancient Babylonian Dragon myth. Mr. Keane goes a step further back, and attempts to account for the origin of this myth. He suggests that it refers to the first settlements on the low-lying plains of Chaldæa, when man had to contend against the periodicial freshets of the Euphrates and Tigris, caused by the melting of the snows of the watersheds, and against huge crocodiles which infested the estuaries. "There could be no peace or progress until the waters were quelled (confined within their banks, and diverted into irrigation canals), and until their presiding genius (the reptile or dragon, "lord of chaos") was overthrown. . . . Then the foremost champions engaged in these contests acquired their apotheosis in the minds of a grateful posterity, while the vanquished enemy assumed more and more the form of unearthly monsters and demons hostile to man. Such memories easily passed on from generation to generation until they acquired consistency and permanency in the written records of the cultured Babylonian peoples."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I TRUST you will give me space—not to continue this discussion—but to correct an error in Mr. Dyer's last letter to you. Mr. Dyer states that I consider that Prof. Weldon's investigation of the crab's carapace "does not satisfy the canons of scientific inquiry." I have made no statement to that effect, and am surprised that Mr. Dyer should put such a phrase into my mouth.

I am, I believe, almost as fully acquainted with the details of Prof. Weldon's work, and the laborious measurements carried out by him in the laboratory at Plymouth and in University College, as is Mr. Dyer. I have never spoken of nor regarded the actual results obtained by Prof. Weldon as otherwise than interesting and valuable. My difference with Prof. Weldon is, as I explained (I thought with sufficient clearness) in my first letter to NATURE on this subject, one as to the interpretation put by him on these results. I do not consider that he is warranted in declaring that a particular frontal proportion of the carapace is effective in securing the survival of those crabs possessing it. Moreover, I do not agree with him in holding it to be "absolutely illogical" (as he expressed himself at the Linnean Society) to entertain the hypothesis that one or more structures in a "surviving" or "naturally-selected" organic form may be effective in bringing about that survival or selection whilst other structures may vary concomitantly with these and be inoperative in effecting the survival.

Utrecht, September 18.

The Position of Science at Oxford.

ON my return to Oxford my attention has been called to an article which appeared in your issue of July 9 last, bearing the above title. (By science is meant, of course, natural science.) I do not wish to discuss the whole of the article. It is for the most part temperately written, and contains some useful criticism by which we in Oxford may profit.

One of its main contentions, however, is this—that hardly any of the colleges at Oxford do much, and that none do more than they are obliged, to encourage natural science by means of their endowments.

I think that if I may be allowed briefly to state what the college which I know best, and the only one for which I have a right to speak, is doing in this matter, it will enable your readers to see that this contention is not universally applicable, and that there are at least some exceptions with regard to which the writer seems very imperfectly informed.

Magdalen College is spending at this moment in the direct endowment of natural science through professorships, fellowships, scholarships, and exhibitions, over £3500 a year, besides maintaining a laboratory of its own, and subsidising in other ways the teaching of natural science both in the University and within its own walls.

We support four professors of natural science. It may be said that we are obliged by statute to do so. That is true, but we were not bound to establish these professorships as rapidly as we have done, and we have been obliged at times to suspend fellowships in order to do so. We have, besides our four professor-fellows, three other fellows on our Governing Body voluntarily elected by the college for natural science.

The writer of the article complains that so few colleges have even a single tutor in natural science. More than twenty-five years ago we started a tutor, and for the last dozen years we have had a lecturer as well in natural science upon our regular staff.

We are not absolutely bound to offer any scholarships for natural science. We have always offered one a year ever since our demyships were thrown open, and we have frequently elected two and sometimes three demies in natural science in the same year, and often exhibitioners as well. Of the two senior demies, which are all we can at present afford ourselves, one was elected for natural science.

I believe that several other colleges at Oxford could point to facts analogously ignored or underrated by the writer of the article. What I have stated will at any rate, I think, show that my college, which was barely alluded to by him, has not been backward to recognise the claims or encourage by endowment the study of the natural sciences at Oxford.

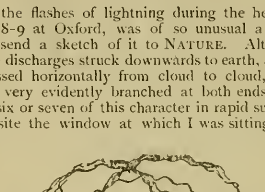
Magdalen College Oxford, September 17.

A Remarkable Lightning Flash.

ONE of the flashes of lightning during the heavy storm of September 8-9 at Oxford, was of so unusual a form that I venture to send a sketch of it to NATURE. Although a good many of the discharges struck downwards to earth, a considerable number passed horizontally from cloud to cloud, and most of these were very evidently branched at both ends. There had been some six or seven of this character in rapid succession in a cloud opposite the window at which I was sitting, and after a



Lightning Flash at Oxford, at about 12.45 a.m. September 9.

pause of two or three minutes I saw the appearance I have tried to represent. From the red glare by which it was surrounded, it was evidently within the cloud, but it was so dazzlingly bright that the after-image remained visible long enough for me to trace the convolutions and sketch them from memory. The main body of the flash made one complete loop, and the two ends, which were much branched, nearly completed a second turn. It appeared almost due north, about 35° above the horizon, and might have been comprised within a circle of about 5° in diameter. Evidently the path of the flash was an irregular spiral, and, with the exception of the branched ends, it looked exactly like the discharge of a large induction coil, seen end on. I much regretted not being provided with a camera.

GEORGE J. BURCH.

21 Norham Road, Oxford, September 9.

A Peculiarity in Perch.

I VENTURE to bring the following observation before the readers of NATURE, because I believe it to be uncommon, and that it will be a matter of interest to naturalists. My brother, whilst fishing in a pond in East Lancashire, caught twelve perch, the smallest weighing 3 ozs. and the largest 10 ozs., and eight of them exhibited a very marked peculiarity.

On the left side of the fish the cover of the gill was very small, being only less than half the natural size, and as a consequence a large portion of the gill was exposed. The largest fish presented this appearance.

The remaining four had covers to their gills, perfectly normal and similar on both sides.

The peculiarities about this malformation are that it apparently is confined to the gill-cover on the left side of the head, the one on the right side being perfectly normal; and is only to be found in certain of the fish in the pond.

It may possibly be the result of a disease; but if this is the case, the fact of it affecting always the same gill-cover appears somewhat remarkable, and to my mind is more than a coincidence. Besides every part of the fish, including the gill-cover itself, appears to be perfectly healthy.

The water has no predominant feature, and gives on analysis results similar to any common spring-water. I have known at rare intervals water containing iron to be discharged into the pond, but this has been almost immediately noticed and prevented.

As I have been unable to find an account of any disease exhibiting such a characteristic as above described, I have come to the conclusion that it is a very peculiar malformation of the cover of the gill. I should be glad to have some further information respecting this phenomenon if any reader of NATURE is in a position to give it.

R. J. FLINTOFF.

The Siemens Gas and Coke Fire.

I HAVE had a Siemens gas and coke fire in my study for fifteen years. There was much trouble in getting it put in properly, and Sir W. Siemens kindly advised me about it. It burns very little gas, and the coke is cheap. The gas is only used to kindle or liven up the coke. Everybody admires the beautiful fire it makes, and there is no smell and no smoke. The coke requires to be broken to the size of a small apple, and it is needful to clear out the bottom of the fire. I do this with an iron shovel, and thus remove the ash which, without this removal, would choke the fire. It is the neglect of this essential process which makes the Siemens fire sometimes a failure. Mine is, in all respects, a brilliant success.

P. W. CLAYDEN.

13 Tavistock Square, September 18.

P.S.—I read of the grate in NATURE in 1880, saw it at the Smoke Abatement Exhibition in 1881, and adopted it at once.

THE LIVERPOOL MEETING OF THE BRITISH ASSOCIATION.

V.

LIVERPOOL, *Wednesday.*

THE dominant note throughout this meeting has been "Listerism"—the germ theory, the application of biology to medicine. The reception given to the President by the people of Liverpool, especially by the medical profession, has been splendid and enthusiastic. The Philharmonic Hall was crowded to the doors by an attentive and appreciative audience on the occasion of the Presidential Address; and the vote of thanks was most appropriately and happily proposed by the Lord Mayor (Lord Derby), and seconded by Sir William Turner, an early friend and colleague of the President.

This is a large meeting, the total number will probably nearly reach 3200, and this will place it as one of the few largest meetings of the Association; it has certainly been one of the busiest and liveliest. The hospitality of Lord Derby, both at the Town Hall and at Knowsley, and the banquets given by the Medical Institution and the American Chamber of Commerce, have been much appreciated.

Notwithstanding the unsettled weather, the garden parties have been largely attended, and have constituted a most agreeable and welcome method of meeting the members of other Sections.

St. George's Hall has been much admired as an unequalled reception-room; and with its new decoration, its beautiful tiled pavement, the electric light, the grand organ, and the crowd of people constantly passing to and fro, has presented a gay and lively scene.

At the Sectional meetings, although there has been nothing sensational, there is much evidence of solid work, and many interesting discussions, such as that on the Röntgen rays, in Section A, where Lenard is a notable figure, and the joint discussions of Sections D and I, on the origin of Vertebrates, following Prof. Gaskell's interesting address.

Among some of the other more interesting events in the Sections which seem to be attracting public attention were Prof. Ramsay on Helium and Argon, Prof. Dewar's account of liquid air, in Section B, the series of arctic papers, including Sir Martin Conway's lecture on Spitzbergen, and Mr. Scott Keltie's account of Nansen, in the Geographical Section, and the discussion, in Section H, on the Mediterranean race and the origin of Mycænean culture. Other attractive items before the Anthropological Section were the question of the age of the Dolmens, opinion being divided as to whether they belong to the Bronze or the Neolithic period, and the discussion on the femur of *Pithecanthropus*, a comparison of this celebrated bone with the femora of savage races showing that all its special characters are already known in human femora. The Section celebrated in an interesting manner the centenary of the Swede, Retzius the elder, the originator of modern methods of craniology.

One characteristic of the Sectional meetings has certainly been the extreme fulness of the programme, the result being that some Sections have had to meet early and continue sitting late; most of them held meetings on the Saturday, and several will have to continue their work well into the Wednesday forenoon.

Mention need not be made of the other scientific communications, as the usual special account of the work of the Sections will appear in future issues of NATURE.

The two conversaziones were brilliant functions, and the impression amongst the visitors seemed to be that the public rooms in Liverpool were very fine in dimensions and decoration. At the first soirée—that given by the Lord Mayor—there were no adventitious attractions beyond the stately reception and the pleasant meeting of friends. At the local committee's soirée in the Museum Library and Art Galleries, where ample accommodation is available, there were short lectures, demonstrations, and various exhibits which attracted much interest. Perhaps one of the finest exhibits was the great collection of models of ships lent by the Cunard, White Star, and other great ocean lines.

Between forty and fifty foreigners have been present, amongst the more notable figures being the botanists, Chodat, Pfitzer and Magnus; the physicists, Lenard and Kohlrausch; the archæologist, Montelius; and the zoologists, Hjort, Delage, and Minot. We have also had de Candolle, Le Conte, Dupuy, Walther, and Count Pfeil.

The Loan Collection in the new Museum of Zoology at University College seems to have been much appreciated. The exhibits in the collection chiefly illustrate papers read before Sections C, D, and H, and several of the Sections have adjourned in the afternoons to the Museum for special demonstrations.

On Saturday, notwithstanding the unsettled weather, all the excursions arranged were successfully carried out, including the dredging expedition in the Lancashire Sea Fisheries steamer, in which a number of the foreigners took part. The applications for the Thursday excursions are sufficiently numerous. The Isle of Man seems to be the favourite one, and as this is to be an expedition of considerable scientific interest, with a carefully-arranged programme, including nearly all the objects worthy of special attention in the island, a further report on the results of the excursion will be given in a future number of NATURE.

On Association Sunday, the usual arrangements were made, and several selected preachers dealt with the inter-relations of religion and science and other subjects which were supposed to be appropriate to the occasion. Amongst those who preached were Dean Farrar, Mr. Lund, Canon Diggle, Dr. Klein, and Prof. Ryle, of Cambridge. Many of the members of the Association seemed to prefer short trips in the neighbourhood of Liverpool, or to take advantage of the pleasant hospitality that was offered by some of the owners of large houses and gardens in the afternoon and evening.

At the meetings of the General Committee, several important matters have been decided. The date of the commencement of the meeting at Toronto next year has been fixed for August 18. The President-elect is Sir John Evans, K.C.B. The list of vice-Presidents and the local officers have also been fixed upon.

The Secretary of the Toronto Committee made a preliminary statement as to the facilities offered by the great steam ship companies in crossing the Atlantic, and the Committee have already distributed to members of the Association a most attractive preliminary programme in the form of a richly-illustrated pamphlet of seventy pages. Further details in regard to the arrangements for crossing the Atlantic, and also for travelling to America, are promised shortly.

With regard to the meeting in 1898, it seemed likely at one time that there would be competition between Glasgow and Bristol. A distinguished deputation from each City Council attended this meeting; but at the last moment the Lord Provost of Glasgow gracefully withdrew his claim in favour of Bristol, which had already made considerable preparations, and had been first in the field; consequently Bristol, on the motion of Sir. F. Bramwell, seconded by Prof. Ramsay, was unanimously fixed upon as the place of meeting for 1898. It was further resolved that the meeting in 1899 be held at Dover, in conjunction with the meeting of the French Association at Boulogne, on the other side of the Channel.

At the meetings of the Committee of Recommendations, the following Committees of the Association with grants of money were reappointed:—

Synopsis of Grants of Money appropriated to Scientific Purposes by the General Committee at the Liverpool Meeting, September, 1896. *The names of the Members entitled to call on the General Treasurer for the respective Grants are prefixed.*

* Re-appointed.

At the final meeting, held on Wednesday, the usual votes of thanks and concluding speeches were made, and the general impression was expressed that the success of the meeting was characterised by the magnificence of the meeting-rooms, the hospitality of the people of Liverpool, and the general liveliness of the proceedings. The British Association certainly seems, from the evidence at this, its latest meeting, to be very full of life and vigour.

W. A. HERDMAN.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY J. E. MARR, M.A., F.R.S., SEC. G.S., PRESIDENT OF THE SECTION.

THE feelings of one who, being but little versed in the economic applications of his science, is called upon to address a meeting of the Association held in a large industrial centre, might, under ordinary circumstances, be of no very pleasant character; but I take courage when I remember that those connected with my native county, in which we are now gathered, have taken prominent part in advancing branches of our science which are not directly concerned with industrial affairs. I am reminded, for instance, that one amongst you, himself a busy professional man, has in his book on "The Origin of Mountain Ranges" given to the world a theoretical work of the highest value; that, on the opposite side of the county, those who are responsible for the formation and management of that excellent educational institution, the Ancoats Museum, have wisely recognised the value of some knowledge of geology as a means of quickening our appreciation of the beauties of nature; and that one who has done solid service to geology by his teachings, who has kept before us the relationship of our science to that which is beautiful—I refer to the distinguished author of "Modern Painters"—has chosen the northern part of the county for his home, and has illustrated his teaching afresh by reference to the rocks of the lovely district around him. Nor can I help referring to one who has recently passed away—the late Sir Joseph Prestwich—the last link between the pioneers of our science and the geologists of the present day, who, though born in London, was of Lancashire family, and whom we may surely therefore claim as one of Lancashire's worthies. With these evidences of the catholicity of taste on the part of geologists connected with the county, I feel free to choose my own subject for this address, and, my time being occupied to a large extent with academic work, I may be pardoned for treating that subject in academic fashion. As I have paid considerable attention to the branch of the science which bears the somewhat uncouth designation of stratigraphical geology, I propose to take the present state of our knowledge of this branch as my theme.

Of the four great divisions of geology, petrology may be claimed as being largely of German origin, the great impetus to its study having been given by Werner and his teachings. Palæontology may be as justly claimed by the French nation, Cuvier having been to so great an extent responsible for placing it upon a scientific basis. Physical geology we may partly regard as our own, the principles laid down by Hutton and supported by Playfair having received illustration from a host of British writers, amongst whom may be mentioned Jukes, Ramsay, and the brothers Geikie; but the grand principles of physical geology have been so largely illustrated by the magnificent and simple features displayed on the other side of the Atlantic, that we may well refer to our American brethren as leaders in this branch of study. The fourth branch, stratigraphical geology, is essentially British as regards origin, and, as every one is aware, its scientific principles were established by William Smith, who was not only the father of English geology, but of stratigraphical geology in general.

Few will deny that stratigraphical geology is the highest branch of the science, for, as has been well said, it "gathers up the sum of all that is made known by the other departments of the science, and makes it subservient to the interpretation of the geological history of the earth." The object of the stratigraphical geologist is to obtain information concerning all physical, climatic, and biological events which have occurred during each period of the past, and to arrange them in chronological order, so as to write a connected history of the earth. If all of this information were at our disposal, we could write a complete earth-history, and the task of the geologist would be ended. As it is, we have barely crossed the threshold of discovery, and the "imperfection of the geological record," like the "glorious uncertainty" of our national game, gives geology one of its great charms. Before passing on to consider more particularly the present state of the subject of our study, a few remarks upon this imperfection of the geological record may not be out of place, seeing that the term has been used by so many modern writers, and its exact signification occasionally misunderstood. The imperfection of the palæontological record is usually understood by the term when used, and it will be considered here as an illustration of the incompleteness of our

knowledge of earth-history; but it must be remembered that the imperfection of the physical record is equally striking, as will be insisted on more fully in the sequel.

Specially prominent amongst the points upon which we are ignorant stands the nature of the Precambrian faunas. The extraordinary complexity of the earliest known Cambrian fauna has long been a matter for surprise, and the recent discoveries in connection with the *Olenellus* fauna do not diminish the feeling.[1] After commenting upon the varied nature of the earliest known fauna, the late Prof. Huxley, in his Address to the Geological Society in 1862, stated that "any admissible hypothesis of progressive modification must be compatible with persistence without progression, through indefinite periods. . . . Should such an hypothesis eventually be proved to be true, . . . the conclusion will inevitably present itself, that the Palæozoic, Mesozoic, and Cainozoic faunæ and floræ, taken together, bear somewhat the same proportion to the whole series of living beings which have occupied this globe, as the existing fauna and flora do to them." Whether or not this estimate is correct, all geologists will agree that a vast period of time must have elapsed before the Cambrian period, and yet our ignorance of faunas existing prior to the time when the *Olenellus* fauna occupied the Cambrian seas is almost complete. True, many Precambrian fossils have been described at various times, but, in the opinion of many competent judges, the organic nature of each one of these requires confirmation. I need not, however, enlarge upon this matter, for I am glad to say we have amongst us a geologist who will at a later stage read a paper before this Section upon the subject of Precambrian fossils, and there is no one better able, owing to his intimate acquaintance with the actual relics, to present fairly and impartially the arguments which have been advanced in favour of the organic origin of the objects which have been appealed to as evidences of organisms of Precambrian age than our revered co-worker from Canada, Sir J. William Dawson. We may look forward with confidence to the future discovery of many faunas older than those of which we now possess certain knowledge, but until these are discovered, the palæontological record must be admitted to be in a remarkably incomplete condition. In the meantime, a study of the recent advance of our knowledge of early life is significant of the mode in which still earlier faunas will probably be brought to light. In 1845, Dr. E. Emmons described a fossil, now known to be an *Olenellus*, though at that time the earliest fauna was supposed to be one containing a much later group of organisms, and it was not until Nathorst and Brögger established the position of the *Olenellus* zone that the existence of a fauna earlier than that of which *Paradoxides* was a member was admitted: and, indeed, the *Paradoxides* fauna itself was proved to be earlier than that containing *Olenus*, long after these two genera had been made familiar to palæontologists, the Swedish palæontologist, Augelin, having referred the *Paradoxides* fauna to a period earlier than that of the one with *Olenus*. It is quite possible, therefore, that fossils are actually preserved in our museums at the present moment, which have been extracted from rocks deposited before the period of formation of the *Olenellus* beds, though their age has not been determined. The *Olenellus* horizon now furnishes us with a datum-line from which we can work backwards, and it is quite possible that the *Neobolus* beds of the Salt Range,[2] which underlie beds holding *Olenellus*, really do contain, as has been maintained, a fauna of date anterior to the formation of the *Olenellus* beds; and the same may be the case with the beds containing the *Protolenus* fauna in Canada,[3] for this fauna is very different from any known in the *Olenellus* beds, or at a higher horizon, though Mr. G. F. Matthew, to whom geologists owe a great debt for his admirable descriptions of the early fossils of the Canadian rocks, speaks very cautiously of the age of the beds containing *Protolenus* and its associates. Notwithstanding our ignorance of Precambrian faunas, valuable work has recently been done in proving the existence of important groups of stratified rocks deposited previously to the formation of the beds containing the earliest known Cambrian fossils; I may refer especially to the proofs of the Precambrian age of the Torridon sandstone of north-west Scotland, lately furnished by the officers of the Geological Survey, and their discovery that the maximum thickness of these strata is over 10,000 feet.[1] Amongst the sediments of this important system, more than one fauna may be discovered, even if most of the strata were accumulated with rapidity, and all geologists must hope that the officers of the Survey—who, following Nicol, Lapworth, and others, have done so much to elucidate the geological structure of the Scottish Highlands—may obtain the legitimate reward of their labours, and definitely prove the occurrence of rich faunas of Precambrian age in the rocks of that region.

But, although we may look forward hopefully to the time when we may lessen the imperfection of the records of early life upon the globe, even the most hopeful cannot expect that record to be rendered perfect, or that it will make any near approach to perfection. The posterior segments of the remarkable trilobite *Mesonacis vermontana* are of a much more delicate character than the anterior ones, and the resemblance of the spine on the fifteenth "body-segment" of this species to the terminal spine of *Olenellus* proper, suggests that in the latter sub-genus posterior segments of a purely membranous character may have existed, devoid of hard parts. If this be so, the entire outer covering of the trilobites, at a period not very remote from the end of Precambrian times, may have been membranous, and the same thing may have occurred with the structures analogous to the hard parts of organisms of other groups. Indeed, with our present views as to development, we can scarcely suppose that organisms acquired hard parts at a very early period of their existence, and fauna after fauna may have occupied the globe, and disappeared, leaving no trace of its existence, in which case we are not likely ever to obtain definite knowledge of the characters of our earliest faunas, and the biologist must not look to the geologist for direct information concerning the dawn of life upon the earth.

Proceeding now to a consideration of the faunas of the rocks formed after Precambrian times, a rough test of the imperfection of the record may be made by examining the gaps which occur in the vertical distribution of forms of life. If our knowledge of ancient faunas were very incomplete, we ought to meet with many cases of recurrence of forms after their apparent disappearance from intervening strata of considerable thickness, and many such cases have actually been described by that eminent palæontologist, M. Barrande, amongst the Palæozoic rocks of Bohemia, though even these are gradually being reduced in number owing to recent discoveries; indeed, in the case of the marine faunas, marked cases of recurrence are comparatively rare, and the occurrence of each form is generally fairly unbroken from its first appearance to its final extinction, thus showing that the imperfection of the record is by no means so marked as might be supposed. Fresh-water and terrestrial forms naturally furnish a large percentage of cases of recurrence, owing to the comparative rarity with which deposits containing such organisms are preserved amongst the strata.

A brief consideration of the main reasons for the present imperfection of our knowledge of the faunas of rocks formed subsequently to Precambrian times may be useful, and suggestive of lines along which future work may be carried out. That detailed work in tracts of country which are yet unexplored, or have been but imperfectly examined by the geologist, will add largely to our stock of information, needs only to be mentioned; the probable importance of work of this kind in the future may be inferred from a consideration of the great increase of our knowledge of the Permo-Carboniferous faunas, as the result of recent labours in remote regions. It is specially desirable that the ancient faunas and floras of tropical regions should be more fully made known, as a study of these will probably throw considerable light upon the influence of climate upon the geographical distribution of organisms in past times. The old floras and faunas of Arctic regions are becoming fairly well known, thanks to the zeal with which the Arctic regions have been explored. But, confining our attention to the geology of our own country, much remains to be done even here, and local observers especially have opportunities of adding largely to our stock of knowledge, a task they have performed so well in the past. To give examples of the value of such work, our knowledge of the fauna of the Cambrian rocks of Britain is largely due to the present President of the Geological Society, when resident at St. David's, whilst

1 Dr. C. D. Walcott, in his monograph on "The Fauna of the Lower Cambrian or Olenellus Zone" (Washington 1890), records the following great groups as represented in the Olenellus beds of America:—Spongiæ, Hydrozoa, Actinozoa, Echinodermata, Annelida? (trails, burrows, and tracks), Brachiopoda, Lamellibranchiata, Gasteropoda, Pteropoda, Crustacea, and Trilobita. Others are known as occurring in beds of the same age in the Old World.

3 G. F. Matthew, "The Protolenus Fauna." *Trans. New York Acad. of Science*, 1895, vol. xiv. p. 101.

1 Sir A. Geikie, "Annual Report of the Geological Survey [United Kingdom] . . . for the year ending December 31, 1893." (London, 1894.)

the magnificent fauna of the Wenlock limestone would have been far less perfectly known than it is, if it were not for the collections of men like the late Colonel Fletcher and the late Dr. Grindrod. Again, the existence of the rich fauna of the Cambridge Greensand would have been unsuspected had not the bed known by that name been worked for the phosphatic nodules which it contains.

It is very desirable that large collections of varieties of species should be made, for in this matter the record is very imperfect. There has been, and, I fear, is still, a tendency to reject specimens when their characters do not conform with those given in specific descriptions, and thus much valuable material is lost. Local observers should be specially careful to search for varieties, which may be very abundant in places where the conditions were favourable for their production, though rare or unknown elsewhere. Thus, I find the late Mr. W. Keeping remarking that "it is noteworthy that at Upware, and indeed all other places known to me, the species of *Brachiopoda* [of the *Neocomian* beds] maintain much more distinctness and isolation from one another than at Brickhill."[1] The latter place appears to be one where conditions were exceptionally favourable in *Neocomian* times for the production of intermediate forms.

A mere knowledge of varieties is, however, of no great use to the collector without a general acquaintance with the morphology of the organisms whose remains he extracts from the earth's strata, and one who has this can do signal service to the science. It is specially important that local observers should be willing to devote themselves to the study of particular groups of organisms, and to collect large suites of specimens of the group they have chosen for study. With a group like the graptolites, for instance, the specimens which are apparently best preserved are often of little value from a morphological point of view, and fragments frequently furnish more information than more complete specimens. These fragments seldom find their way to our museums, and accordingly we may examine a large suite of graptolites in those museums without finding any examples showing particular structures of importance, such as the sac-like bodies carried by many of these creatures. As an illustration of the value of work done by one who has made a special study of a particular group of organisms, I may refer to the remarkable success achieved by the late Mr. Norman Glass in developing the calcareous supports of the brachial processes of Brachiopods. Work of this character will greatly reduce the imperfection of the record from the biologists' point of view.

The importance of detailed work leads one to comment upon the general methods of research which have been largely adopted in the case of the stratified rocks. The principle that strata are identifiable by their included organisms is the basis of modern work, as it was of that which was achieved by the father of English Geology, and the identification of strata in this manner has of recent years been carried out in very great detail, notwithstanding the attempt on the part of some well-known writers to show that correlation of strata in great detail is impossible. The objection to this detailed work is mainly founded upon the fact that it must take time for an organism or group of organisms to migrate from one area to another, and therefore it was stated that they cannot have lived contemporaneously in two remote areas. But the force of this objection is practically done away with if it can be shown that the time taken for migration is exceedingly short as compared with the time of duration of an organism or group of organisms upon the earth, and this has been shown in the only possible way—namely, by accumulating a very great amount of evidence as the result of observation. The eminent writers referred to above, who were not trained geologists, never properly grasped the vast periods of time which must have elapsed during the occurrence of the events which it is the geologist's province to study. An historian would speak of events which began at noon on a certain day and ended at midnight at the close of that day as contemporaneous with events which commenced and ended five minutes later, and this is quite on a par with what the geologist does when correlating strata. Nevertheless, there are many people who still view the task of correlating minute subdivisions of stratified systems with one another, with a certain amount of suspicion, if not with positive antipathy; but the work must be done for all that. Brilliant generalisations are attractive as well as valuable, but the steady accumulation of facts is as necessary for the advancement of the science as it was in the days when the Geological Society was founded, and its members applied themselves "to multiply and record observations, and patiently to await the result at some future period." I have already suggested a resemblance between geology and cricket, and I may be permitted to point out that just as in the game the free-hitter wins the applause, though the patient "stone-waller" often wins the match, so, in the science, the man apt at brilliant generalisations gains the approval of the general public, but the patient recorder of apparently insignificant details adds matter of permanent value to the stores of our knowledge. In the case of stratigraphical geology, if we were compelled to be content with correlation of systems only, and were unable to ascertain which of the smaller series and stages were contemporaneous, but could only speak of these as "homotaxial," we should be in much the same position as the would-be antiquary who was content to consider objects fashioned by the Romans as contemporaneous with those of mediæval times. Under such circumstances geology would indeed be an uncertain science, and we should labour in the field, knowing that a satisfactory earth-history would never be written. Let us hope that a brighter future is in store for us, and let me urge my countrymen to continue to study the minute subdivisions of the strata, lest they be left behind by the geologists of other countries, to whom the necessity for this kind of study is apparent, and who are carrying it on with great success.

The value of detailed work on the part of the stratigraphical geologist is best grasped if we consider the recent advance that has been made in our science owing to the more or less exhaustive survey of the strata of various areas, and the application of the results obtained to the elucidation of earth's history. A review of this nature will enable us not only to see what has been done, but also to detect lines of inquiry which it will be useful to pursue in the future; but it is obvious that the subject is so wide that little more can be attempted than to touch lightly upon some of the more prominent questions. A work might well be written treating of the matters which I propose to notice. We have all read our "Principles of Geology," or "The Modern Changes of the Earth and its Inhabitants considered as illustrative of Geology," to quote the alternative title; some day we may have a book written about the ancient changes of the earth and its inhabitants considered as illustrative of geography.

Commencing with a glance at the light thrown on inorganic changes by a detailed examination of the strata, I may briefly allude to advances which have recently been made in the study of denudation. The minor faults, which can only be detected when the small subdivisions of rock-groups are followed out carefully on the ground, have been shown to be of great importance in defining the direction in which the agents of denudation have operated, as demonstrated by Prof. W. C. Brögger, for instance, in the case of the Christiania Fjord (*Nyt. Mag. for Naturvidensk.*, vol. xxx. (1886), p. 79); and I have recently endeavoured to prove that certain valleys in the English Lake District have been determined by shattered belts of country, the existence of which is shown by following thin bands of strata along their outcrop. The importance of the study of the strata in connection with the genesis and subsequent changes of river-systems is admirably brought out in Prof. W. M. Davis's paper on "The Development of certain English Rivers (*Geograph. Journ.*, vol. v. (1895) p. 127), a paper which should be read by all physical geologists; it is, indeed, a starting-point of kindred work which remains especially for local observers to accomplish. Study of this kind not only adds to our knowledge of the work of geological agencies, but helps to diminish the imperfection of the record, for the nature of river-systems, when rightly understood, enables us to detect the former presence of deposits over areas from which they have long since been removed by denudation.

An intimate acquaintance with the lithological characters of the strata of a district affords valuable information in connection with the subject of glacial denudation. The direction of glacial transport over the British Isles has been largely inferred from a study of the distribution of boulders of igneous rock, whilst those of sedimentary rock have been less carefully observed. The importance of the latter is well shown by the work which has been done in Northern Europe in tracing the Scandinavian boulders to their sources, a task which could not have been performed successfully if the Scandinavian strata had not been

[1] W. Keeping, Sedgwick Essay: "The Fossils and Palæontological Affinities of the Neocomian Deposits of Upware and Brickhill." (Cambridge, 1883.)

studied in great detail.[1] I shall presently have more to say with regard to work connected with the lithological characters of the sediments. Whilst mentioning glacial denudation, let me allude to a piece of work which should be done in great detail, though it is not, strictly speaking, connected with stratigraphy, namely, the mapping of the rocks around asserted "rock-basins." I can find no actual proof of the occurrence of such basins in Britain, and it is very desirable that the solid rocks and the drift should be carefully inserted on large-scale maps, not only all around the shores of several lakes, but also between the lakes and the sea, in order to ascertain whether the lakes are really held in rock-basins. Until this work is done, however probable the occurrence of rock-basins in Britain may be considered to be, their actual existence cannot be expected to be proved.

When referring to the subject of denudation, mention was made a moment ago of the study of the lithological character of the sediments. Admirable work in this direction was carried out years ago by one who may be said to have largely changed the direction of advance of geology in this country owing to his researches "On the Microscopical Structure of Crystals, indicating the Origin of Minerals and Rocks." I refer, of course, to Dr. H. C. Sorby. But since our attention has been so largely directed to petrology, the study of the igneous and metamorphic rocks has been most zealously pursued, whilst that of the sediments has been singularly little heeded, with few exceptions, prominent amongst which is the work of Mr. Maynard Hutchings, the results of which have been recently published in the *Geological Magazine*, though we must all hope that the details which have hitherto been supplied to us, valuable as they are, are only a foretaste of what is to follow from the pen of this able observer. Descriptions of the lithological changes which occur in a vertical series of sediments, as well as of those which are observed when any particular band is traced laterally, will no doubt throw light upon a number of interesting questions.

Careful work amongst the ancient sediments, especially those which are of organic origin, has strikingly illustrated the general identity of characters, and therefore of methods of formation, of deposits laid down on the sea-floors of past times and those which are at present in course of construction. Globigerine-oozes have been detected at various horizons and in many countries. Prof. H. Alleyne Nicholson (Nicholson and Lydekker, "Manual of Palæontology," chap. ii.) has described a pteropod-ooze of Devonian age in the Hamilton Limestone of Canada, which is largely composed of the tests of *Styliola*: and to Dr. G. J. Hinde we owe the discovery of a large number of radiolarian cherts of Palæozoic and Neozoic ages in various parts of the globe. The extreme thinness of many argillaceous deposits, which are represented elsewhere by hundreds of feet of strata, suggests that some of them, at any rate, may be analogous to the deep-sea clays of modern oceans, though in the case of deposits of this nature we must depend to a large extent upon negative evidence. The uniformity of character of thin marine deposits over wide areas is in itself evidence of their formation at some distance from the land; but although the proofs of origin of ancient sediments far from coast-lines may be looked upon as permanently established, the evidence for their deposition at great depths below the ocean's surface might be advantageously increased in the case of many of them. The fairly modern sediments, containing genera which are still in existence, are more likely to furnish satisfactory proofs of a deep-sea origin than are more ancient deposits. Thus the existence of *Archæopneustes* and *Cystechinus* in the oceanic series of Barbadoes, as described by Dr. Gregory, furnishes strong proofs of the deep-sea character of the deposits, whilst the only actual argument in favour of the deep-sea character of certain Palæozoic sediments has been put forward by Prof. Suess, who notes the similarity of certain structures of creatures in ancient rocks to those possessed by modern deep-sea crustacea, especially the co-existence of trilobites which are blind with those which have enormously developed eyes.

A question which has been very prominently brought to the fore in recent years is that of the mode of formation of certain coral-reefs. The theory of Charles Darwin, lately so widely accepted as an explanation of the mode of formation of barrier-reefs and atolls, has been, as is well known, criticised by Dr. Murray, with the result that a large number of valuable observations have been recently made on modern reefs, especially by biologists, as a contribution to the study of reef formation. Nor have geologists been inactive. Dr. E. Mojsisovics and Prof. Dupont, to mention two prominent observers, have described knoll-like masses of limestone more or less analogous, as regards structure, to modern coral-reefs. They consider that these have been formed by corals, and indeed Dupont maintains that the atoll-shape is still recognisable in ancient Devonian coral-reefs in Belgium.[1] I would observe that all cases of "knoll-reefs" of this character have been described in districts which furnish proofs of having been subjected to considerable orogenic disturbance, subsequent to the formation of the rocks composing the knoll-shaped masses, whilst in areas which have not been affected by violent earth-foldings, the reef-building corals, so far as I have been able to ascertain, give rise to sheet-like masses, such as should be produced according to Dr. Murray's theory. I would mention especially the reefs of the Corallian Rocks of England, and also some admirable examples seen amongst the Carboniferous Limestone strata of the great western escarpment of the Pennine chain which faces the Eden valley in the neighbourhood of Melmerby in Cumberland. Considering the number of dissected coral-reefs which exist amongst the strata of the earth's crust, and the striking way in which their structure is often displayed, it is rather remarkable that comparatively little attention has been paid to them by geologists in general, when the subject has been so prominently brought before the scientific world, for we must surely admit that we are much more likely to gain important information, shedding light upon the methods of reef-formation, by a study of such dissected reefs, than by making a few bore-holes on some special coral island. I would specially recommend geologists to make a detailed study of the British coral-reefs of Silurian, Devonian, Carboniferous, and Jurassic ages.

Turning now to organic deposits of vegetable origin, we must, as the result of detailed work, be prepared to admit the inapplicability of any one theory of the formation of coal seams. The "growth-in-place" theory may be considered fairly well established for some coals, such as the spore-coals, whilst the "drift" theory furnishes an equally satisfactory explanation of the formation of cannel-coal. It is now clear that the application of the general term *coal* to a number of materials of diverse nature, and probably of diverse origin, was largely responsible for the dragging-out of a controversy, in which the champions of either side endeavoured to explain the origin of all coal in one particular way.

The stratigraphical geologist, attempting to restore the physical geography of former periods, naturally pays much attention to the positions of ancient coast-lines; indeed, all teachers find it impossible to give an intelligible account of the stratified rocks without some reference to the distribution of land and sea at the time of their formation. The general position of land-masses at various times has been ascertained in several parts of the world, but much more information must be gathered together before our restorations of ancient sea-margins approximate to the truth. The carboniferous rocks of Britain have been specially studied with reference to the distribution of land and water during the period of their accumulation, and yet we find that owing to the erroneous identification of certain rocks of Devonshire as grits or sandstones, which Dr. Hinde has shown to be radiolarian cherts, land was supposed to lie at no great distance south of this region in Lower Carboniferous times, whereas the probabilities are in favour of the existence of an open ocean at a considerable distance from any land in that direction. This case furnishes us with an excellent warning against generalisation upon insufficient data.

As a result of detailed study of the strata, the effects of earth-movements have been largely made known to us, especially of those comparatively local disturbances spoken of as orogenic which are mainly connected with mountain-building, whilst information concerning the more widely spread epeirogenic movements is also furnished by a study of the stratified rocks. The structure of the Alps, of the North-West Highlands of Scotland, and of the uplifted tracts of North America is now familiar to geologists, whilst the study of comparatively recent sediments has proved the existence of widespread and extensive movements in times which are geologically modern; for instance,

[1] It is desirable that the boulders of sedimentary rock imbedded in the drifts of East Anglia should be carefully examined and fossils collected from them. The calcareous strata associated with the Alum Shales of Scandinavia and the strata of the Orthoceras-Limestone of that region may be expected to be represented amongst the boulders.

[1] Similar knoll-like masses have been described in this country by Mr. R. H. Tiddeman, as occurring in the Craven district of Yorkshire, but he does not attribute their formation to coral growth to any great extent.

the deep-water deposits of late Tertiary age found in the West Indies indicate the occurrence of considerable uplift in that region. But a great amount of work yet remains to be done in this connection, especially concerning horizontal distortion of masses of the earth's crust, owing to more rapid horizontal advance of one portion than of another, during periods of movement. Not until we gather together a large amount of information derived from actual inspection of the rocks shall we be able to frame satisfactory theories of earth-movement, and in the meantime we are largely dependent upon the speculations of the physicist, often founded upon very imperfect data, on which is built an imposing superstructure of mathematical reasoning. We have been told that our continents and ocean-basins have been to a great extent permanent as regards position through long geological ages; we now reply by pointing to deep-sea sediments of nearly all geological periods, which have been uplifted from the ocean-abysses to form portions of our continents; and as the result of study of the distribution of fossil organisms, we can point almost as confidently to the sites of old continents now sunk down into the ocean depths. It seems clear that our knowledge of the causes of earth-movements is still in its infancy, and that we must be content to wait awhile, until we have further information at our disposal.

Recent work has proved the intimate connection betwixt earth-movement and the emission and intrusion of igneous rocks, and the study of igneous rocks has advanced beyond the petrographical stage; the rocks are now made to contribute their share towards the history of different geological periods. The part which volcanic action has played in the actual formation of the earth's crust is well exemplified in Sir Archibald Geikie's Presidential Addresses to the Geological Society, wherein he treats of the former volcanic history of the British Isles. (*Quart. Journ. Geol. Soc.*, vols. xlvii. and xlviii.) The way in which extruded material contributes to the formation of sedimentary masses has, perhaps, not been fully grasped by many writers, who frequently seem to assume that deposition is a measure of denudation, and *vice versâ*, whereas deposition is only a measure of denudation, and of the material which has been ejected in a fragmental condition from the earth's interior, which in some places forms a very considerable percentage of the total amount of sediment.

The intruded rocks also throw much light on past earth-history, and I cannot give a better illustration of the valuable information which they may furnish to the stratigraphical geologist when rightly studied, than by referring to the excellent and suggestive work by my colleague, Mr. Alfred Harker, on the Bala Volcanic Rocks of Carnarvonshire. (*Sedgwick Essay* for 1888: Camb. Univ. Press, 1889.)

Perhaps the most striking instance of the effect which detailed stratigraphical work has produced on geological thought is supplied by the study of the crystalline schists. Our knowledge of the great bulk of the rocks which enter into the formation of a schistose complex is not very great, but the mode of production of many of them is now well known, and the crude speculations of some of the early geologists are now making way for theories founded on careful and minute observations in the field as well as in the laboratory. Recent work amongst the crystalline schists shows, furthermore, how careful we should be not to assume that because we have got at the truth, we have therefore ascertained the whole truth. We all remember how potent a factor dynamic metamorphism was supposed to be, owing to discoveries made in the greatly disturbed rocks of Scotland and Switzerland; and the action of heat was almost ignored by some writers, except as a minor factor, in the production of metamorphic change. The latest studies amongst the foliated rocks tend to show that heat does play a most important part in the manufacture of schists. The detailed work of Mr. George Barrow, in North-East Forfarshire (*Quart. Journ. Geol. Soc.*, vol. xlix. (1893) p. 330) has already thrown a flood of light upon the origin of certain schists, and their connection with igneous rocks, and geologists will look forward with eagerness to further studies of the puzzling Highland rocks by this keen observer.

The subject of former climatic conditions is one in which the geologist has very largely depended upon followers of other branches of science for light, and yet it is one peculiarly within the domain of the stratigraphical geologist; and information which has already been furnished concerning former climatic conditions, as the result of careful study of the strata, is probably only an earnest of what is to follow when the specialist in climatology pays attention to the records of the rocks, and avoids the theories elaborated in the student's sanctum. The recognition of an Ice Age in Pleistocene times at once proved the fallacy of the supposition that there has been a gradual fall in temperature throughout geological ages without any subsequent rise, and accordingly most theories which have been put forward to account for former climatic change have been advanced with special reference to the Glacial period or periods, although there are many other interesting matters connected with climate with which the geologist has to deal. Nevertheless, the occurrence of glacial periods is a matter of very great interest, and one which has deservedly received much attention, though the extremely plausible hypothesis of Croll, and the clear manner in which it has been presented to general readers, tended to throw other views into the shade, until quite recently, when this hypothesis has been controverted from the point of view of the physicist. In the meantime considerable advance has been made in our actual knowledge, and this year, probably for the first time, and as the result of the masterly *résumé* of Prof. Edgworth David ("Evidences of Glacial Action in Australia in Permo-Carboniferous Time," *Quart. Journ. Geol. Soc*, vol. lii. p. 289), the bulk of British geologists are prepared to admit that there has been more than one glacial period, and that the evidence of glacial conditions in the southern hemisphere in Permo-Carboniferous times is established. Croll's hypothesis of course requires the recurrence of glacial periods, but leaving out of account arguments not of a geological character, which have been advanced against this hypothesis, the objection raised by Messrs. Gray and Kendall ("The Cause of an Ice Age," *Brit. Assoc. Rep.* (1892), p. 708), that in the case of the Pleistocene Ice Age "the cold conditions came on with extreme slowness, the refrigerations being progressive from the Eocene period to the climax," seems to me to be a fatal one. At the same time, rather than asking with the above writers "the aid of astronomers and physicists in the solution of" this problem, I would direct the attention of stratigraphical geologists to it, believing that, by steady accumulation of facts, they are more likely than any one else to furnish the true clue to the solution of the glacial problem.

I have elsewhere called attention to marked changes in the faunas of the sedimentary rocks when passing from lower to higher levels, without the evidence of any apparent physical break, or any apparent change in the physical conditions, so far as can be judged from the lithological characters of the strata, and have suggested that such sudden faunistic variations may be due to climate. I refer to the matter as one which may well occupy the attention of local observers.

One of the most interesting points connected with climatic conditions is that of the former general lateral distribution of organisms, and its dependence upon the distribution of climatic zones. The well-known work of the late Dr. Neumayr ("Ueber klimatische Zonen wahrend der Jura-und Kreidezeit," *Denkschr. der math.-naturwissen. Classe der k. k. Akad. der Wissenschaften*, vol. xlvii. Vienna, 1883) has, in the opinion of many geologists, established the existence of climatic zones whose boundaries ran practically parallel with the equator in Jurassic and Cretaceous times, and the possible existence of similar climatic zones in Palæozoic times has been elsewhere suggested; but it is very desirable that much more work should be done upon this subject, and it can only be carried out by paying close attention to the vertical and lateral distribution of organisms in the stratified rocks.

So far we have chiefly considered the importance of stratigraphical geology in connection with the inorganic side of nature. We now come to the bearing of detailed stratigraphical work upon questions concerning the life of the globe, and here the evidence furnished by the geologist particularly appeals to the general educated public as well as to students of other sciences.

Attention has just been directed to the probable importance of former climatic changes in determining the distribution of organisms, but the whole subject of the geographical distribution of organisms during former geological periods, though it has already received a considerable amount of attention, will doubtless have much further light thrown upon it as the result of careful observations carried out amongst the stratified rocks.

So long ago as 1853, Pictet laid it down as a palæontological law that "the geographical distribution of species found in the strata was more extended than the range of species of existing faunas." One would naturally expect that at a time when the diversity of animal organisation was not so great as it now is, the species, having fewer enemies with which to cope, and on the whole not too complex organisations to be affected by out-

ward circumstances, would spread further laterally than they now do; but as we know that in earliest Cambrian times the diversity of organisation was very considerable, it is doubtful whether any appreciable difference would be exerted upon lateral distribution then and now, owing to this cause. At the time at which Pictet wrote, the rich fauna of the deeper parts of the oceans, with its many widely distributed forms of life, was unknown, and the range in space of early organisms must have then struck every one who thought upon the subject as being greater than that of the shallow-water organisms of existing seas, which were alone known. It is by no means clear, however, with our present knowledge, that Pictet's supposed law holds good, and it will require a considerable amount of work before it can be shown to be even apparently true. Our lists of the fossils of different areas are not sufficiently complete to allow us to generalise with safety, but a comparison of the faunas of Australia and Britain indicates a larger percentage of forms common to the two areas, as we examine higher groups of the geological column. If this indication be fully borne out by further work, it will not prove the actual truth of the law, for the apparent wider distribution of ancient forms of life might be due to the greater probability of elevation of ancient deep-sea sediments than of more modern ones which have not been subjected to so many elevatory movements. Still, if the law be apparently true, it is a matter of some importance to geologists; and I have touched upon the matter here in order once again to emphasise the possibility of correlating comparatively small thicknesses of strata in distant regions by their included organisms.

Mention of Pictet's laws, one of which states that fossil animals were constructed upon the same plan as existing ones, leads me to remark upon the frequent assumption that certain fossils are closely related to living groups, when the resemblances between the hard parts of the living and extinct forms are only of the most general character. There is a natural tendency to compare a fossil with its nearest living ally, but the comparison has probably been often pushed too far, with the result that biologists have frequently been led to look for the ancestors of one living group exclusively amongst forms of life which are closely related to those of another living group. The result of detailed work is to bring out more and more prominently the very important differences between some ancient forms and any living creature, and to throw doubts on certain comparisons; thus I find several of the well-known fossils of the Old Red Sandstone, formerly referred without hesitation to the fishes, are now doubtfully placed in that class.

The importance of detailed observation in the field is becoming every day more apparent, and the specialist who remains in his museum examining the collections amassed by the labours of others, and never notes the mode of occurrence of fossils in the strata, will perhaps soon be extinct, himself an illustration of the principle of the survival of the fittest. In the first place, such a worker can never grasp the true significance of the changes wrought on fossil relics after they have become entombed in the strata, especially amongst those rocks which have been subjected to profound earth-movements; and it is to be feared that many "species" are still retained in our fossil lists, whose supposed specific characters are due to distortion by pressure. But a point of greater importance is, that one who confines his attention to museums, cannot, unless the information supplied to him be very full, distinguish the differences between fossils which are variations from a contemporaneous dominant form, such as "sports," and those which have been termed "mutations," which existed at a later period than the forms which they resemble. The value of the latter to those who are attempting to work out phylogenies is obvious, and their nature can only be determined as the result of very laborious and accurate field-work; but such labour in such a cause is well worth performing. The student of phylogeny has had sufficient warning of the dangers which beset his path, from an inspection of the various phylogenetic trees, constructed mainly after study of existing beings only, so

> ". . . like the borealis race,
> That flit ere you can point their place,"

but recent researches amongst various groups of fossil organisms have further illustrated the danger of theorising upon insufficient data, especially suggestive being the discovery of closely similar forms which were formerly considered to be much more nearly related than now proves to be the case; thus Dr. Mojsisovics (*Abhandl. der k. k. geol. Reichsanst.*, vol. vi., 1893) has shown that Ammonites once referred to the same species are specifically distinct, though their hard parts have acquired similar structures, sometimes contemporaneously, sometimes at different times, and Mr. S. S. Buckman (*Quart. Journ. Geol. Soc.*, vol. li. p. 456, 1895) has observed the same thing, which he speaks of as "heterogenetic homœomorphy" in the case of certain brachiopods, whilst Prof. H. A. Nicholson and I (*Geol. Mag.*, December 4, 1895, vol. ii. p. 531) have given reasons for supposing that such heterogenetic homœomorphy, in the case of the graptolites, has sometimes caused the inclusion in one genus of forms which have arisen from two distinct genera. As the result of careful work, dangers of the nature here suggested will be avoided, and our chances of indicating lines of descent correctly will be much increased. It must be remembered that however plausible the lines of descent indicated by students of recent forms may be, the actual links in the chains can only be discovered by examination of the rocks, and it is greatly to be desired that more of our geologists, who have had a thorough training in the field, should receive in addition one as thorough in the zoological laboratory. Shall I be forgiven if I venture on the opinion that a certain suspicion which some of my zoological fellow countrymen have of geological methods, is due to their comparative ignorance of palæontology, and that it is as important for them to obtain some knowledge of the principles of geology as it is for the stratigraphical palæontologist to study the soft parts of creatures whose relatives he finds in the stratified rocks?

The main lines along which the organisms of some of the larger groups have been developed, have already been indicated by several palæontologists, and detailed work has been carried out in several cases. As examples, let me allude to the trilobites, of which a satisfactory natural classification was outlined by the great Barrande in those volumes of his monumental work which deal with the fossils of this order, whilst further indication of their natural inter-relationships has been furnished by Messrs. C. D. Walcott, G. F. Matthew, and others; to the graptolites, whose relationships have been largely worked out by Prof. C. Lapworth, *facile princeps* amongst students of the *Graptolitoidea*, to whom we look for a full account of the phylogeny of the group; to the brachiopods, which have been so ably treated by Dr. C. E. Beecher ("Development of the Brachiopoda," *Amer. Journ. Sci.*, ser. iii. vol. xli. (1891) p. 343, and vol. xliv. (1892) p. 133), largely from a study of recent forms, but also after careful study of those preserved in the fossil state; and to the echinids and lamellibranchs, whose history is being extensively elucidated by Dr. R. T. Jackson ("Phylogeny of the Pelecypoda," *Mem. Boston Soc. Nat. Hist.*, vol. iv. (1890) p. 277; and "Studies of Palæechinoidea," *Bull. Geol. Soc. Amer.*, vol. vii. (1896) p. 171), by methods somewhat similar to those pursued by Dr. Beecher. I might give other instances,[1] but have chosen some striking ones, four of which especially illustrate the great advances which are being made in the study of the palæontology of the invertebrates by our American brethren.

I have occupied the main part of my address with reasons for the need of conducting stratigraphical work with minute accuracy. Many of you may suppose that the necessity for working in this way is so obvious that it is a work of supererogation to insist upon it at great length; but experience has taught me that many geologists consider that close attention to details is apt to deter workers from arriving at important generalisations, in the present state of our science. A review of the past history of the science shows that William Smith, and those who followed after him, obtained their most important results by steady application to details, and subsequent generalisation, whilst the work of those who theorise on insufficient data is apt to be of little avail, though often demanding attention on account of its very daring, and because of the power of some writers to place erroneous views in an attractive light, just as

> ". . . the sun can fling
> Colours as bright on exhalations bred
> By weedy pool or pestilential swamp,
> As on the rivulet, sparkling where it runs,
> Or the pellucid lake."

[1] *E.g.* The following papers treating of the Cephalopoda:—A. Hyatt, "Genesis of the Arietidæ," Smithsonian Contributions, vol. xxvi. (1889); M. Neumayr, Jura-Studien I., "Ueber Phylloceraten," *Jahrb. der k. k. Geol. Reichsanst*, vol. xxi. (1871) p. 297; L. Würtenberger, "Studien übe die Stammesgeschichte der Ammoniten," Leipzig, 1880; S. S. Buckman, "A Monograph of the Inferior Oolite Ammonites of the British Islands, 1887 (*Monogr. Palæontographical Soc.*).

Nor is there any reason to suppose that it will be otherwise in the future, and I am not one of those who consider that the brilliant discoveries were the exclusive reward of the pioneers in our science, and that labourers of the present day must be contented with the gleanings of their harvest; on the contrary, the discoveries which await the geologist will probably be as striking as are those which he has made in the past. The onward march of science is a rhythmic movement, with now a period of steady labour, anon a more rapid advance in our knowledge. It would perhaps be going too far to say that, so far as our science is concerned, we are living in a period rather of the former than of the latter character, though no great geological discovery has recently affected human thought in the way in which it was affected by the proofs of the antiquity of man, and by the publication of "The Origin of Species." If, however, we are to some extent gathering materials, rather than drawing far-reaching conclusions from them, I believe this is largely due to the great expansion which our science has undergone in recent years. It has been said that geology is "not so much one science, as the application of all the physical sciences to the examination and description of the structure of the earth, the investigation of the agencies concerned in the production of that structure, and the history of their action"; and the application of other sciences to the elucidation of the history of our globe has been so greatly extended of recent years, that we are apt to lose sight of the fact that geology is in itself a science, and that it is the special province of the geologist to get his facts at first hand from examination of the earth. The spectroscope and the telescope tell the geologist much; but his proper instrument is the hammer, and the motto of every geologist should be that which has been adopted for the Geological Congress, *Mente et malleo.*

At the risk of being compared to a child playing with edged tools, I cannot help referring to the bearing of modern stratigraphical research on the suggested replacement of a school of uniformitarianism by one of evolution. The distinguished advocate of Evolutionism, who addressed the Geological Society in 1869 upon the modern schools of geological thought, spoke of the school of evolution as though it were midway between those of uniformitarianism and catastrophism, as indeed it is logically, though, considering the tenets of the upholders of catastrophism, as opposed to those of uniformitarianism, at the time of that address, there is no doubt that evolutionism was rather a modification of the uniformitarianism of the period than intermediate between it and catastrophism, which was then practically extinct, at any rate in Britain. One of my predecessors in this chair, speaking upon this subject, says that "the good old British ship 'Uniformity,' built by Hutton and refitted by Lyell, has won so many glorious victories in the past, and appears still to be in such excellent fighting trim, that I see no reason why she should haul down her colours, either to 'catastrophe' or 'evolution.'" It may be so; but I doubt the expediency of nailing those colours to the mast. That Lyell, in his great work, proved that the agents now in operation, working with the same activity as that which they exhibit at the present day, *might* produce the phenomena exhibited by the stratified rocks, seems to be generally admitted, but that is not the same thing as proving that they *did* so produce them. Such proof can only be acquired by that detailed examination of the strata which I have advocated in this address, and at the time that the last edition of the "Principles" appeared, our knowledge of the strata was far less complete than it has subsequently become. It appears to me that we should keep our eyes open to the possibility of many phenomena presented by rocks, even newer than the Archæan rocks, having been produced under different conditions from those now prevalent. The depths and salinity of the oceans, the heights and extent of continents, the conditions of volcanic action, and many other things may have been markedly different from what they are at present, and it is surely unphilosophical to assume conditions to have been generally similar to those of the present day, on the slender data at our disposal. Lastly, uniformitarianism, in its strictest sense, is opposed to rhythmic recurrence of events. "Rhythm is the rule with nature; she abhors uniformity more than she does a vacuum," wrote Prof. Tyndall, many years ago, and the remark is worth noting by geologists. Why have we no undoubted signs of glacial epochs amongst the strata from early Cambrian times to the Great Ice Period, except in Permo-Carboniferous times? Is there not an apparent if not a real absence of manifestation of volcanic activity over wide areas of the earth in Mesozoic times? Were not Devonian, Permo-Triassic, and Miocene times periods of mountain-building over exceptionally wide areas, whilst the intervening periods were rather marked by quiet depression and sedimentation? A study of the evidence available in connection with questions like these suggests rhythmic recurrence. Without any desire to advocate hasty departure from our present methods of research, I think it should be clearly recognised that evolution may have been an important factor in changing the conditions even of those times of which the geologist has more direct knowledge. In this, as in many other questions, it is best to preserve an open mind; indeed, I think that geologists will do well to rest satisfied without an explanation to many problems, amongst them the one just referred to; and that working hypotheses, though useful, are better retained in the manuscript notebooks of the workers than published in the *Transactions* of Learned Societies, whence they filter out into popular works, to the great delight of a sceptical public should they happen to be overthrown.

May I trespass upon your patience for one moment longer? As a teacher of geology, with many years' experience in and out of a large University, I have come to the conclusion that geology is becoming more generally recognised as a valuable instrument of education. The memory, the reasoning faculties, and the powers of observation are alike quickened. The work in the open air, which is inseparable from a right understanding of the science, keeps the body in healthy condition. But over and above these benefits, the communing with nature, often in her most impressive moods, and the insignificance of events in a man's lifetime, as compared with the ceaseless changes through the long æons which have gone before, so influence man's moral nature, that they drive out his meaner thoughts and make him "live in charity with all men."

SECTION D.

ZOOLOGY.

Opening Address by Prof. E. B. Poulton, F.R.S., President of the Section.

A very brief study of the proceedings of this Section in byegone years will show that Presidents have exercised a very wide choice in the selection of subjects. At the last meeting of the Association in this city in 1870 the Biological Section had as its President the late Prof. Rolleston, a man whose remarkable personality made a deep impression upon all who came under his influence, as I have the strongest reason for remembering, inasmuch as he was my first teacher in zoology, and I attended his lectures when but little over seventeen. His address was most characteristic, glancing over a great variety of subjects, literary as well as scientific, and abounding in quotations from several languages, living and dead. A very different style of address was that delivered by the distinguished zoologist who presided over the meeting. Prof. Huxley took as his subject "The History of the Rise and Progress of a Single Biological Doctrine."

Of these two types I selected the latter as my example, and especially desired to attempt the discussion, however inadequate, of some difficulty which confronts the zoologist at the very outset, when he begins to reason from the facts around him—a difficulty which is equally obvious and of equal moment to the highly-trained investigator and the man who is keenly interested in the results obtained by others, but cannot himself lay claim to the position and authority of a skilled observer—to the naturalist and to one who follows some other branch of knowledge, but is interested in the progress of a sister science.

Two such difficulties were alluded to by Lord Salisbury in his interesting presidential address to the British Association at Oxford in 1894, when he spoke of "two of the strongest objections to the Darwinian explanation" of evolution—viz. the theory of natural selection—as appearing "still to retain all their force." The first of these objections was the insufficiency of the time during which the earth has been in a habitable state, as calculated by Lord Kelvin and Prof. Tait, 100 million years being conceded by the former, but only 10 million by the latter. Lord Salisbury quite rightly stated that for the evolution of the organic world as we know it by the slow process of natural selection at least many hundred million years are required;

whereas, "if the mathematicians are right, the biologists cannot have what they demand. . . . The jelly-fish would have been dissipated in steam long before he had had a chance of displaying the advantageous variation which was to make him the ancestor of the human race."

The second objection was that "we cannot demonstrate the process of natural selection in detail; we cannot even, with more or less ease, imagine it." "In natural selection who is to supply the breeder's place?" "There would be nothing but mere chance to secure that the advantageously varied bridegroom at one end of the wood should meet the bride, who by a happy contingency had been advantageously varied in the same direction at the same time at the other end of the wood. It would be a mere chance if they ever knew of each other's existence—a still more unlikely chance that they should resist on both sides all temptations to a less advantageous alliance. But unless they did so the new breed would never even begin, let alone the question of its perpetuation after it had begun."

Prof. Huxley, in seconding the vote of thanks to the President, said that he could imagine that certain parts of the address might raise a very good discussion in one of the Sections, and I have little doubt that he referred to these criticisms and to this Section. When I had to face the duty of preparing this address, I could find no subjects better than those provided by Lord Salisbury.

At first the second objection seemed to offer the more attractive subject. It was clear that the theory of natural selection as held by Darwin was misconceived by the speaker, and that the criticism was ill-aimed. Darwin and Wallace, from the very first, considered that the minute differences which separate individuals were of far more importance than the large single variations which occasionally arise—Lord Salisbury's advantageously varied bride and bridegroom at opposite ends of the wood. In fact, after Fleeming Jenkins's criticisms in the *North British Review* for June 1867, Darwin abandoned these large single variations altogether. Thus he wrote in a letter to Wallace February 2, 1869): "I always thought individual differences more important; but I was blind, and thought single variations might be preserved much oftener than I now see is possible or probable. I mentioned this in my former note merely because I believed that you had come to a similar conclusion, and I like much to be in accord with you." ("Life and Letters," vol. iii.) Hence we may infer that the other great discoverer of natural selection had come to the same conclusion at an even earlier date. But this fact removes the whole point from the criticism I have just quoted. According to the Darwin-Wallace theory of natural selection, individuals sufficiently advantageously varied to become the material for a fresh advance when an advance became necessary, and at other times sufficient to maintain the ground previously gained—such individuals existed not only at the opposite ends of the wood, but were common enough in every colony within its confines. The mere fact that an individual had been able to reach the condition of a possible bride or bridegroom would count for much. Few will dispute that such individuals "have already successfully run the gauntlet of by far the greatest dangers which beset the higher animals [and, it may be added, the lower animals also]—the dangers of youth. Natural selection has already pronounced a satisfactory verdict upon the vast majority of animals which have reached maturity." (Poulton, "Colours of Animals," p. 308.)

But the criticism retains much force when applied to another theory of evolution by the selection of large and conspicuous variations, a theory which certain writers have all along sought to add to or substitute for that of Darwin. Thus Huxley from the very first considered that Darwin had burdened himself unnecessarily in rejecting *per saltum* evolution so unreservedly. (See his letter to Darwin, November 23, 1859; "Life and Letters," vol. ii.) And recently this view has been revived by Bateson's work on variation and by the writings of Francis Galton. I had at first intended to attempt a discussion of this view, together with Lord Salisbury's and other objections which may be urged against it; but the more the two were considered, the more pressing became the claims of the criticism alluded to at first—the argument that the history of our planet does not allow sufficient time for a process which all its advocates admit to be extremely slow in its operation. I select this subject because of its transcendent importance in relation to organic evolution, and because I hope to show that the naturalist has something of weight to contribute to the controversy which has been waged intermittently ever since Lord Kelvin's paper "On Geological Time"[1] appeared in 1868. It has been urged by the great worker and teacher who occupied the Presidential Chair of this Association when it last met in this city that biologists have no right to take part in this discussion. In his Anniversary Address to the Geological Society in 1869 Huxley said: "Biology takes her time from geology. . . . If the geological clock is wrong, all the naturalist will have to do is to modify his notions of the rapidity of change accordingly." This contention is obviously true as regards the time which has elapsed since the earliest fossiliferous rocks were laid down. For the duration of the three great periods we must look to the geologist; but the question as to whether the whole of organic evolution is comprised within these limits, or, if not, what proportion of it is so contained, is a question for the naturalist. The naturalist alone can tell the geologist whether his estimate is sufficient, or whether it must be multiplied by a small or by some unknown but certainly high figure, in order to account for the evolution of the earliest forms of life known in the rocks. This, I submit, is a most important contribution to the discussion.

Before proceeding further it is right to point out that obviously these arguments will have no weight with those who do not believe that evolution is a reality. But although the causes of evolution are greatly debated, it may be assumed that there is no perceptible difference of opinion as to evolution itself, and this common ground will bear the weight of all the zoological arguments we shall consider to-day.

It will be of interest to consider first how the matter presented itself to naturalists before the beginning of this controversy on the age of the habitable earth. I will content myself with quotations from three great writers on biological problems—men of extremely different types of mind, who yet agreed in their conclusions on this subject.

In the original edition of the "Origin of Species" (1859), Darwin, arguing from the presence of trilobites, Nautilus, Lingula, &c., in the earliest fossiliferous rocks, comes to the following conclusion (pages 306, 307): "Consequently, if my theory be true, it is indisputable that before the lowest Silurian stratum was deposited long periods elapsed, as long as, or probably far longer than, the whole interval from the Silurian age to the present day; and that during these vast yet quite unknown periods of time the world swarmed with living creatures."

The depth of his conviction in the validity of this conclusion is seen in the fact that the passage remains substantially the same in later editions, in which, however, Cambrian is substituted for Silurian, while the words "yet quite unknown" are omitted, as a concession, no doubt, to Lord Kelvin's calculations, which he then proceeds to discuss, admitting as possible a more rapid change in organic life, induced by more violent physical changes. (Sixth ed., 1872, p. 286.)

We know, however, that such concessions troubled him much, and that he was really giving up what his judgment still approved. Thus he wrote to Wallace on April 14, 1869: "Thomson's views of the recent age of the world have been for some time one of my sorest troubles. . . ." And again, on July 12, 1871, alluding to Mivart's criticisms, he says: "I can say nothing more about missing links than what I have said. I should rely much on pre-Silurian times; but then comes Sir W. Thomson, like an odious spectre."

Huxley's demands for time in order to account for pre-Cambrian evolution, as he conceived it, were far more extensive. Although in 1869 he bade the naturalist stand aside and take no part in the controversy, he had nevertheless spoken as a naturalist in 1862, when, at the close of another Anniversary Address to the same Society, he argued from the prevalence of persistent types "that any admissible hypothesis of progressive modification must be compatible with persistence without progression through indefinite periods"; and then maintained that "should such an hypothesis eventually be proved to be true . . . the conclusion will inevitably present itself that the Palæozoic, Mesozoic, and Cainozoic faunæ and floræ, taken together, bear somewhat the same proportion to the whole series of living beings which have occupied this globe as the existing fauna and flora do to them."

[1] *Trans. Geol. Soc.*, Glasgow, vol. iii. See also "On the Age of the Sun's Heat," *Macmillan*, March 1862: reprinted as Appendix to Thomson and Tait, "Natural Philosophy," vol. i. part 2, second edition; and "On the Secular Cooling of the Earth," Royal Society of Edinburgh, 1862.

Herbert Spencer, in his article on "Illogical Geology" in the *Universal Review* for July 1859 (reprinted in his "Essays," 1868, vol. i., pp. 324–376), uses these words: "Only the last chapter of the earth's history has come down to us. The many previous chapters, stretching back to a time immeasurably remote, have been burnt, and with them all the records of life we may presume they contained." Indeed, so brief and unimportant does Herbert Spencer consider this last chapter to have been that he is puzzled to account for "such evidences of progression as exist"; and finally concludes that they are of no significance in relation to the doctrine of evolution, but probably represent the succession of forms by which a newly upheaved land would be peopled. He argues that the earliest immigrants would be the lower forms of animal and vegetable life, and that these would be followed by an irregular succession of higher and higher forms, which "would thus simulate the succession presented by our own sedimentary series."

We see, then, what these three great writers on evolution thought on this subject: they were all convinced that the time during which the geologists concluded that the fossiliferous rocks had been formed was utterly insufficient to account for organic evolution.

Our object to-day is first to consider the objections raised by physicists against the time demanded by the geologist, and still more against its multiplication by the student of organic evolution; secondly, to inquire whether the present state of palæontological and zoological knowledge increases or diminishes the weight of the threefold opinion quoted above—an opinion formed on far more slender evidence than that which is now available. And if we find this opinion sustained, it must be considered to have a very important bearing upon the controversy.

The arguments of the physicists are three:—

First, the argument from the observed secular change in the length of the day the most important element of which is due to tidal retardation. It has been known for a very long time that the tides are slowly increasing the length of our day. Huxley explains the reason with his usual lucidity: "That this must be so is obvious, if one considers, roughly, that the tides result from the pull which the sun and the moon exert upon the sea, causing it to act as a sort of break upon the solid earth." (Anniv. Address to Geol. Soc., 1869.)

A liquid earth takes a shape which follows from its rate of revolution, and from which, therefore, its rate of revolution can be calculated.

The liquid earth consolidated in the form it last assumed, and this shape has persisted until now, and informs us of the rate of revolution at the time of consolidation. Comparing this with the present rate, and knowing the amount of lengthening in a given time due to tidal friction, we can calculate the date of consolidation as certainly less than 1000 million years ago.

This argument is fallacious, as many mathematicians have shown. The present shape tells us nothing of the length of the day at the date of consolidation; for the earth, even when solid, will alter its form when exposed for a long time to the action of great forces. As Prof. Perry said in a letter to Prof. Tait (NATURE, January 3, 1895): "I know that solid rock is not like cobbler's wax, but 1000 million years is a very long time, and the forces are great." Furthermore, we know that the earth is always altering its shape, and that whole coast-lines are slowly rising or falling, and that this has been true, at any rate, during the formation of the stratified rocks.

This argument is dead and gone. We are, indeed, tempted to wonder that the physicist, who was looking about for arguments by which to revise what he conceived to be the hasty conclusions of the geologist as to the age of the earth, should have exposed himself to such an obvious retort in basing his own conclusions as to its age on the assumption that the earth, which we know to be always changing in shape, has been unable to alter its equatorial radius by a few miles under the action of tremendous forces constantly tending to alter it, and having 1000 million years in which to do the work.

With this flaw in the case it is hardly necessary to insist on our great uncertainty as to the rate at which the tides are lengthening the day.

The spectacle presented by the geologist and biologist, deeply shocked at Lord Kelvin's extreme uniformitarianism in the domain of astronomy and cosmic physics, is altogether too comforting to be passed by without remark; but in thus indulging in a friendly *tu quoque*, I am quite sure that I am speaking for every member of this Section in saying that we are in no way behind the members of Section A in our pride and admiration at the noble work which he has done for science, and we are glad to take this opportunity of congratulating him on the half-century of work and teaching—both equally fruitful—which has reached its completion in the present year.

The second argument is based upon the cooling of the earth, and this is the one brought forward and explained by Lord Salisbury in his Presidential Address. It has been the argument on which perhaps the chief reliance has been placed, and of which the data—so it was believed—were the least open to doubt.

On the Sunday during the meeting of the British Association at Leeds (1890), I went for a walk with Prof. Perry, and asked him to explain the physical reasons for limiting the age of the earth to a period which the students of other sciences considered to be very inadequate. He gave me an account of the data on which Lord Kelvin relied in constructing this second argument, and expressed the strong opinion that they were perfectly sound, while, as for the mathematics, it might be taken for granted, he said, that they were entirely correct. He did not attach much weight to the other arguments, which he regarded as merely offering support to the second.

This little piece of personal history is of interest, inasmuch as Prof. Perry has now provided us with a satisfactory answer to the line of reasoning which so fully satisfied him in 1890. And he was led to a critical examination of the subject by the attitude taken up by Lord Salisbury in 1894. Prof. Perry was not present at the meeting, but when he read the President's address, and saw how other conclusions were ruled out of court, how the only theory of evolution which commands anything approaching universal assent was set on one side because of certain assumptions as to the way in which the earth was believed to have cooled, he was seized with a desire to sift these assumptions, and to inquire whether they would bear the weight of such far-reaching conclusions. Before giving the results of his examination, it is necessary to give a brief account of the argument on which so much has been built.

Lord Kelvin assumed that the earth is a homogeneous mass of rock similar to that with which we are familiar on the surface. Assuming, further, that the temperature increases, on the average 1° F. for every 50 feet of depth near the surface everywhere, he concluded that the earth would have occupied not less than twenty, nor more than four hundred, million years in reaching its present condition from the time when it first began to consolidate and possessed a uniform temperature of 7000° F.

If, in the statement of the argument, we substitute for the assumption of a homogeneous earth an earth which conducts heat better internally than it does towards the surface, Prof. Perry, whose calculations have been verified by Mr. O. Heaviside, finds that the time of cooling has to be lengthened to an extent which depends upon the value assigned to the internal conducting power. If, for instance, we assume that the deeper part of the earth conducts ten times as well as the outer part, Lord Kelvin's age would require to be multiplied by fifty-six. Even if the conductivity be the same throughout, the increase of density in the deeper part, by augmenting the capacity for heat of unit volume, implies a longer age than that conceded by Lord Kelvin. If the interior of the earth be fluid or contain fluid in a honeycomb structure, the rate at which heat can travel would be immensely increased by convection currents, and the age would have to be correspondingly lengthened. If, furthermore, such conditions, although not obtaining now, did obtain in past times, they will have operated in the same direction.

Prof. Tait, in his letter to Prof. Perry (published in NATURE of January 3, 1895), takes the entirely indefensible position that the latter is bound to prove the higher internal conductivity. The obligation is all on the other side, and rests with those who have pressed their conclusions hard and carried them far. These conclusions have been, as Darwin found them, one of our "sorest troubles"; but when it is admitted that there is just as much to be said for another set of assumptions leading to entirely different conclusions, our troubles are at an end, and we cease to be terrified by an array of symbols, however unintelligible to us. It would seem that Prof. Tait, without, as far as I can learn, publishing any independent calculations of the age of the earth, has lent the weight of his authority to a period of ten million years, or half of Lord Kelvin's minimum. But

in making this suggestion he apparently feels neither interest nor responsibility in establishing the data of the calculations which he borrowed to obtain therefrom a very different result from that obtained by their author.

Prof. Perry's object was not to substitute a more correct age for that obtained by Lord Kelvin, but rather to show that the data from which the true age could be calculated are not really available. We obtain different results by making different assumptions, and there is no sufficient evidence for accepting one assumption rather than another. Nevertheless, there is some evidence which indicates that the interior of the earth in all probability conducts better than the surface. Its far higher density is consistent with the belief that it is rich in metals, free or combined. Prof. Schuster concludes that the internal electric conductivity must be considerably greater than the external. Geologists have argued from the amount of folding to which the crust has been subjected that cooling must have taken place to a greater depth than 120 miles, as assumed in Lord Kelvin's argument. Prof. Perry's assumption would involve cooling to a much greater depth.

Prof. Perry's conclusion that the age of the habitable earth is lengthened by increased conductivity is the very reverse of that to which we should be led by a superficial examination of the case. Prof. Tait, indeed, in the letter to which I have already alluded, has said: "Why, then, drag in mathematics at all, since it is absolutely obvious that the better conductor the interior in comparison with the skin, the longer ago must it have been when the whole was at 7000° F., the state of the skin being as at present?" Prof. Perry, in reply, pointed out that one mathematician who had refuted the tidal retardation argument (Rev. M. H. Close, in R. Dublin Soc., February 1878), had assumed that the conditions described by Prof. Tait would have involved a shorter period of time. And it is probable that Lord Kelvin thought the same; for he had assumed conditions which would give the result—so he believed at the time—most acceptable to the geologist and biologist. Prof. Perry's conclusion is very far from obvious, and without the mathematical reasoning would not be arrived at by the vast majority of thinking men.

The "natural man" without mathematics would say, so far from this being "absolutely obvious," it is quite clear that increased conductivity, favouring escape of heat, would lead to more rapid cooling, and would make Lord Kelvin's age even shorter.

The argument can, however, be put clearly without mathematics, and, with Prof. Perry's help, I am able to state it in a few words. Lord Kelvin's assumption of an earth resembling the surface rock in its relations to heat leads to the present condition of things, namely, a surface gradient of 1° F. for every 50 feet, in 100,000,000 years, more or less. Deeper than 150 miles he imagines that there has been almost no cooling. If, however, we take one of the cases put by Prof. Perry, and assume that below a depth of four miles there is ten times the conductivity, we find that after a period of 10,000,000,000 years the gradient at the surface is still 1° F. for every 50 feet; but that we have to descend to a depth of 1500 miles before we find the initial temperature of 7000° F. undiminished by cooling. In fact the earth, as a whole, has cooled far more quickly than under Lord Kelvin's conditions, the greater conductivity enabling a far larger amount of the internal heat to escape; but in escaping it has kept up the temperature gradient at the surface.

Lord Kelvin, replying to Prof. Perry's criticisms, quite admits that the age at which he had arrived by the use of this argument may be insufficient. Thus, he says, in his letter (NATURE, January 3, 1895): "I thought my range from 20 millions to 400 millions was probably wide enough, but it is quite possible that I should have put the superior limit a good deal higher, perhaps 4000 instead of 400."

The third argument was suggested by Helmholtz, and depends on the life of the sun. If the energy of the sun is due only to the mutual gravitation of its parts, and if the sun is now of uniform density, "the amount of heat generated by his contraction to his present volume would have been sufficient to last 18 million years at his present rate of radiation." (Newcomb's "Popular Astronomy," p. 523). Lord Kelvin rejects the assumption of uniform density, and is, in consequence of this change, able to offer a much higher upward limit of 500 million years

This argument also implies the strictest uniformitarianism as regards the sun. We know that other suns may suddenly gain a great accession of energy, so that their radiation is immensely increased. We only detect such changes when they are large and sudden, but they prepare us to believe that smaller accessions may be much more frequent, and perhaps a normal occurrence in the evolution of a sun. Such accessions may have followed from the convergence of a stream of meteors. Again, it is possible that the radiation of the sun may have been diminished and his energy conserved by a solar atmosphere.

Newcomb has objected to these two possible modes by which the life of the sun may have been greatly lengthened, that a lessening of the sun's heat by under a quarter would cause all the water on the earth to freeze, while an increase of much over half would probably boil it all away. But such changes in the amount of radiation received would follow from a greater distance from the sun of $15\frac{1}{2}$ per cent., and a greater proximity to him of 18·4 per cent., respectively. Venus is inside the latter limit, and Mars outside the former, and yet it would be a very large assumption to conclude that all the water in the former is steam, and all in the latter ice. Indeed, the existence of water and the melting of snow on Mars are considered to be thoroughly well authenticated. It is further possible that in a time of lessened solar radiation the earth may have possessed an atmosphere which would retain a larger proportion of the sun's heat; and the internal heat of the earth itself, great lakes of lava under a canopy of cloud for example, may have played an important part in supplying warmth.

Again we have a greater age if there was more energy available than in Helmholtz's hypothesis. Lord Kelvin maintains that this is improbable because of the slow rotation of the sun, but Perry has given reasons for an opposite conclusion.

The collapse of the first argument of tidal retardation, and of the second of the cooling of the earth, warn us to beware of a conclusion founded on the assumption that the sun's energy depends, and has ever depended, on a single source of which we know the beginning and the end. It may be safely maintained that such a conclusion has not that degree of certainty which justifies the followers of one science in assuming that the conclusion of other sciences must be wrong, and in disregarding the evidence brought forward by workers in other lines of research.

We must freely admit that this third argument has not yet fully shared the fate of the two other lines of reasoning. Indeed, Prof. George Darwin, although attacking these latter, agrees with Lord Kelvin in regarding 500 million years as the maximum life of the sun. (*British Association Reports*, 1886, pp. 514–518.)

We may observe, too, that 500 million years is by no means to be despised: a great deal may happen in such a period of time. Although I should be very sorry to say that it is sufficient, it is a very different offer from Prof. Tait's 10 million.

In drawing up this account of the physical arguments, I owe almost everything to Prof. Perry for his articles in NATURE (January 3 and April 18, 1895), and his kindness in explaining any difficulties that arose. I have thought it right to enter into these arguments in some detail, and to consume a considerable proportion of our time in their discussion. This was imperatively necessary, because they claimed to stand as barriers across our path, and, so long as they were admitted to be impassable, any further progress was out of the question. What I hope has been an unbiassed examination has shown that, as barriers, they are more imposing than effective: and we are free to proceed, and to look for the conclusions warranted by our own evidence. In this matter we are at one with the geologists; for, as has already been pointed out, we rely on them for an estimate of the time occupied by the deposition of the stratified rocks, while they rely on us for a conclusion as to how far this period is sufficient for the whole of organic evolution.

First, then, we must briefly consider the geological argument, and I cannot do better than take the case as put by Sir Archibald Geikie in his Presidential Address to this Association at Edinburgh in 1892.

Arguing from the amount of material removed from the land by denuding agencies, and carried down to the sea by rivers, he showed that the time required to reduce the height of the land by one foot, varies, according to the activity of the agencies at work, from 730 years to 6800 years. But this also supplies a

measure of the rate of deposition of rock; for the same material is laid down elsewhere, and would of course add the same height of one foot to some other area equal in size to that from which it was removed.

The next datum to be obtained is the total thickness of the stratified rocks from the Cambrian system to the present day. "On a reasonable computation these stratified masses, where most fully developed, attain a united thickness of not less than 100,000 feet. If they were all laid down at the most rapid recorded rate of denudation, they would require a period of seventy-three millions of years for their completion. If they were laid down at the slowest rate, they would demand a period of not less than 680 millions."

The argument that geological agencies acted much more vigorously in past times he entirely refuted by pointing to the character of the deposits of which the stratified series is composed. "We can see no proof whatever, nor even any evidence which suggests that on the whole the rate of waste and sedimentation was more rapid during Mesozoic and Palæozoic time than it is to-day. Had there been any marked difference in this rate from ancient to modern times, it would be incredible that no clear proof of it should have been recorded in the crust of the earth."

It may therefore be inferred that the rate of deposition was no nearer the more rapid than the slower of the rates recorded above, and, if so, the stratified rocks would have been laid down in about 400 million years.

There are other arguments favouring the uniformity of conditions throughout the time during which the stratified rocks were laid down, in addition to those which are purely geological and depend upon the character of the rocks themselves. Although more biological than geological, these arguments are best considered here.

The geological agency to which attention is chiefly directed by those who desire to hurry up the phenomena of rock formation is that of the tides. But it seems certain that the tides were not sufficiently higher in Silurian times to prevent the deposition of certain beds of great thickness under conditions as tranquil as any of which we have evidence in the case of a formation extending over a large area. From the character of the organic remains it is known that these beds were laid down in the sea, and there are the strongest grounds for believing that they were accumulated along shores and in fairly shallow water. The remains of extremely delicate organisms are found in immense numbers, and over a very large area. The recent discovery, in the Silurian system of America, of trilobites, with their long delicate antennæ perfectly preserved, proves that in one locality (Rome, New York State) the tranquillity of deposition was quite as profound as in any locality yet discovered on this side of the Atlantic.

There are, then, among the older Palæozoic rocks a set of deposits than which we can imagine none better calculated to test the force of the tides; and we find that they supply evidence for exceptional tranquillity of conditions over a long period of time.

There is other evidence of the permanence, throughout the time during which the stratified rocks were deposited, of conditions not very dissimilar from those which obtain to-day. Thus the attachments of marine organisms, which are permanently rooted to the bottom or on the shores, did not differ in strength from those which we now find—an indication that the strains due to the movements of the sea did not greatly differ in the past.

We have evidence of a somewhat similar kind to prove uniformity in the movements of the air. The expanse of the wings of flying organisms certainly does not differ in a direction which indicates any greater violence in the atmospheric conditions. Before the birds had become dominant among the larger flying organisms, their place was taken by the flying reptiles, the pterodactyls, and before the appearance of these we know that, in Palæozoic times, the insects were of immense size, a dragon-fly from the Carboniferous rocks of France being upwards of two feet in the expanse of its wings. As one group after another of widely dissimilar organisms gained control of the air, each was in turn enabled to increase to the size which was best suited to such an environment, but we find that the limits which obtain to-day were not widely different in the past. And this is evidence for the uniformity in the strains due to wind and storm no less than to those due to gravity. Furthermore, the condition of the earth's surface at present shows us how extremely sensitive the flying organism is to an increase in the former of these strains, when it occurs in proximity to the sea. Thus it is well known that an unusually large proportion of the Madeiran beetles are wingless, while those which require the power of flight possess it in a stronger degree than on continental areas. This evolution in two directions is readily explained by the destruction by drowning of the winged individuals of the species which can manage to live without the power of flight, and of the less strongly winged individuals of those which need it. Species of the latter kind cannot live at all in the far more stormy Kerguelen Land, and the whole of the insect fauna is wingless.

The size and strength of the trunks of fossil trees afford, as Prof. George Darwin has pointed out, evidence of uniformity in the strains due to the condition of the atmosphere.

We can trace the prints of raindrops at various geological horizons, and in some cases found in this country it is even said that the eastern side of the depressions is the more deeply pitted, proving that the rain drove from the west, as the great majority of our storms do to-day.

When, therefore, we are accused of uniformitarianism, as if it were an entirely unproved assumption, we can at any rate point to a large body of positive evidence which supports our contention, and the absence of any evidence against it. Furthermore, the data on which we rely are likely to increase largely, as the result of future work.

After this interpolation, chiefly of biological argument in support of the geologist, I cannot do better than bring the geological evidence to a close in the words which conclude Sir Archibald Geikie's address: "After careful reflection on the subject, I affirm that the geological record furnishes a mass of evidence which no arguments drawn from other departments of nature can explain away, and which, it seems to me, cannot be satisfactorily interpreted save with an allowance of time much beyond the narrow limits which recent physical speculation would concede."

In his letter to Prof. Perry (NATURE, January 3, 1895), Lord Kelvin says:—

"So far as underground heat alone is concerned, you are quite right that my estimate was 100 million, and please remark (*P. L. and A.*, vol. ii. p. 87) that that is all Geikie wants; but I should be exceedingly frightened to meet him now with only 20 million in my mouth."

We have seen, however, that Geikie considered the rate of sedimentation to be, on the whole, uniform with that which now obtains, and this would demand a period of nearly 400 million years. He points out furthermore that the time must be greatly increased on account of the breaks and interruptions which occur in the series, so that we shall probably get as near an estimate as is possible from the data which are available by taking 450 million as the time during which the stratified rocks were formed.

Before leaving this part of the subject, I cannot refrain from suggesting a line of enquiry which may very possibly furnish important data for checking the estimates at present formed by geologists, and which, if the mechanical difficulties can be overcome, is certain to lead to results of the greatest interest and importance. Ever since the epoch-making voyage of the *Challenger*, it has been known that the floor of the deep oceans outside the yellow shelf which fringes the continental areas is covered by a peculiar deposit formed entirely of meteoric and volcanic dust, the waste of floating pumice, and the hard parts of animals living in the ocean. Of these latter only the most resistant can escape the powerful solvent agencies. Many observations prove that the accumulation of this deposit is extremely slow. One indication of this is especially convincing: the teeth of sharks and the most resistant part of the skeleton—the ear-bones—of whales are so thickly spread over the surface that they are continually brought up in the dredge, while sometimes a single haul will yield a large number of them. Imagine the countless generations of sharks and whales which must have succeeded each other in order that these insignificant portions of them should be so thickly spread over that vast area which forms the ocean floor. We have no reason to suppose that sharks and whales die more frequently in the deep ocean than in the shallow fringing seas; in fact, many observations point in the opposite direction, for wounded and dying whales often enter shallow creeks and inlets, and not uncommonly become stranded. And yet these remains of sharks and whales, although well known in the stratified rocks which were laid down in

comparatively shallow water and near coasts, are only found in certain beds, and then in far less abundance than in the oceanic deposit. We can only explain this difference by supposing that the latter accumulate with such almost infinite slowness as compared with the continental deposits that these remains form an important and conspicuous constituent of the one, while they are merely found here and there when looked for embedded in the other. The rate of accumulation of all other constituents is so slow as to leave a layer of teeth and ear-bones uncovered, or covered by so thin a deposit that the dredge can collect them freely. Dr. John Murray calculates that only a few inches of this deposit have accumulated since the Tertiary Period. These most interesting facts prove furthermore that the great ocean basins and continental areas have occupied the same relative positions since the formation of the first stratified rocks; for no oceanic deposits are found anywhere in the latter. We know the sources of the oceanic deposit, and it might be possible to form an estimate, within wide limits, of its rate of accumulation. If it were possible to ascertain its thickness by means of a boring, some conclusions as to the time which has elapsed during the lifetime of certain species—perhaps even the lifetime of the oceans themselves—might be arrived at. Lower down the remains of earlier species would probably be found. The depth of this deposit and its character at deeper levels are questions of overwhelming interest; and perhaps even more so is the question as to what lies beneath. Long before the *Challenger* had proved the persistence of oceanic and continental areas, Darwin, with extraordinary foresight, and opposed by all other naturalists and geologists, including his revered teacher, Lyell, had come to the same conclusion. His reasoning on the subject is so convincing that it is remarkable that he made so few converts, and this is all the more surprising since the arguments were published in the "Origin of Species," which in other respects produced so profound an effect. In speculating as to the rocks in which the remains of the ancestors of the earliest known fossils may still exist, he suggested that, although the existing relationship between the positions of our present oceans and continental areas is of immense antiquity, there is no reason for the belief that it has persisted for an indefinite period, but that at some time long antecedent to the earliest known fossiliferous rocks "continents may have existed where oceans are now spread out; and clear and open oceans may have existed where our continents now stand." Not the least interesting result would be the test of this hypothesis, which would probably be forthcoming as the result of boring into the floor of a deep ocean; for although, as Darwin pointed out, it is likely enough that such rocks would be highly metamorphosed, yet it might still be possible to ascertain whether they had at any time formed part of a continental deposit, and perhaps to discover much more than this. Such an undertaking might be carried out in conjunction with other investigations of the highest interest, such as the attempt to obtain a record of the swing of a pendulum at the bottom of the ocean.

We now come to the strictly biological part of our subject—to the inquiry as to how much of the whole scheme of organic evolution has been worked out in the time during which the fossiliferous rocks were formed, and how far, therefore, the time required by the geologist is sufficient.

It is first necessary to consider Lord Kelvin's attempt to rescue us from the dilemma in which we were placed by the insufficiency of time for evolution—the suggestion that life may have reached the earth on a meteorite. According to this view, the evolution which took place elsewhere may have been merely completed, in a comparatively brief space of time, on our earth.

We know nothing of the origin of life here or elsewhere, and our only attitude towards this or any other hypothesis on the subject is that of the anxious inquirer for some particle of evidence. But a few brief considerations will show that no escape from the demands for time can be gained in this way.

Our argument does not deal with the time required for the origin of life, or for the development of the lowest beings with which we are acquainted from the first formed beings, of which we know nothing. Both these processes may have required an immensity of time; but as we know nothing whatever about them, and have as yet no prospect of acquiring any information, we are compelled to confine ourselves to as much of the process of evolution as we can infer from the structure of living and fossil forms—that is, as regards animals, to the development of the simplest into the most complex Protozoa, the evolution of the Metazoa from the Protozoa, and the branching of the former into its numerous Phyla, with all their Classes, Orders, Families, Genera, and Species. But we shall find that this is quite enough to necessitate a very large increase in the time estimated by the geologist.

The Protozoa, simple and complex, still exist upon the earth in countless species, together with the Metazoan Phyla. Descendants of forms which in their day constituted the beginning of that scheme of evolution which I have defined above, descendants, furthermore, of a large proportion of those forms which, age after age, constituted the shifting phases of its onward progress, still exist, and in a sufficiently unmodified condition to enable us to reconstruct, at any rate in mere outline, the history of the past. Innumerable details and many phases of supreme importance are still hidden from us, some of them perhaps never to be recovered. But this frank admission, and the eager and premature attempts to expound too much, to go further than the evidence permits, must not be allowed to throw an undeserved suspicion upon conclusions which are sound and well supported, upon the firm conviction of every zoologist that the general trend of evolution has been, as I have stated it, that each of the Metazoan Phyla originated, directly or indirectly, in the Protozoa.

The meteorite theory would, however, require that the process of evolution went backward on a scale as vast as that on which it went forward, that certain descendants of some central type, coming to the earth on a meteorite, gradually lost their Metazoan complexity and developed backward into the Protozoa, throwing off the lower Metazoan Phyla on the way, while certain other descendants evolved all the higher Metazoan groups. Such a process would shorten the period of evolution by half, but it need hardly be said that all available evidence is entirely against it.

The only other assumption by means of which the meteorite hypothesis would serve to shorten the time is even more wild and improbable. Thus it might be supposed that the evolution which we believe to have taken place on this earth, really took place elsewhere—at any rate as regards all its main lines—and that samples of all the various phases, including the earliest and simplest, reached us by a regular meteoric service, which was established at some time after the completion of the scheme of organic evolution. Hence the evidences which we study would point to an evolution which occurred in some unknown world with an age which even Prof. Tait has no desire to limit.

If these wild assumptions be rejected, there remains the supposition that, if life was brought by a meteorite, it was life no higher than that of the simplest Protozoon—a supposition which leaves our argument intact. The alternative supposition, that one or more of the Metazoan Phyla were introduced in this way while the others were evolved from the terrestrial Protozoa, is hardly worth consideration. In the first place, some evidence of a part in a common scheme of evolution is to be found in every Phylum. In the second place, the gain would be small; the arbitrary assumption would only affect the evidence of the time required for evolution derived from the particular Phylum or Phyla of supposed meteoric origin.

The meteoric hypothesis, then, can only affect our argument by making the most improbable assumptions, for which, moreover, not a particle of evidence can be brought forward.

We are therefore free to follow the biological evidence fearlessly. It is necessary, in the first place, to expand somewhat the brief outline of the past history of the animal kingdom, which has already been given. Since the appearance of the "Origin of Species," the zoologist, in making his classifications, has attempted as far as possible to set forth a genealogical arrangement. Our purpose will be served by an account of the main outlines of a recent classification, which has been framed with a due consideration for all sides of zoological research, new and old, and which has met with general approval. Prof. Lankester divides the animal kingdom into two grades, the higher of which, the Enterozoa (Metazoa), were derived from the lower, the Plastidozoa (Protozoa). Each of these grades is again divided into two sub-grades, and each of these is again divided into Phyla, corresponding more or less to the older Sub-Kingdoms. Beginning from below, the most primitive animals in existence are found in the seven Phyla of the lower Protozoan sub-grade, the Gymnomyxa. Of these unfortunately only two, the Reticularia (Foraminifera) and Radiolaria, possess a structure which renders possible their preservation in the

rocks. The lowest and simplest of these Gymnomyxa represent the starting-point of that scheme of organic evolution which we are considering to-day. The higher order of Protozoan life, the sub-grade Corticata, contains three Phyla, no one of which is available in the fossil state. They are, however, of great interest and importance to us as showing that the Protozoan type assumes a far higher organisation on its way to evolve the more advanced grade of animal life. The first-formed of these latter are contained in the two Phyla of the sub-grade Cœlentera, the Porifera or Sponges, and the Nematophora or Corals, Sea-Anemones, Hydrozoa and allied groups. Both of these Phyla are plentifully represented in the fossil state. It is considered certain that the latter of these, the Nematophora, gave rise to the higher sub-grade, the Cœlomata, or animals with a cœlom or body-cavity surrounding the digestive tract. This latter includes all the remaining species of animals in nine Phyla, five of which are found fossil—the Echinoderma, Gephyrea, Mollusca, Appendiculata, and Vertebrata.

Before proceeding further, I wish to lay emphasis on the immense evolutionary history which must have been passed through before the ancestor of one of the higher of these nine Phyla came into being. Let us consider one or two examples, since the establishment of this position is of the utmost importance for our argument. First, consider the past history of the Vertebrata—of the common ancestor of our Balanoglossus, Tunicates, Amphioxus, Lampreys, Fishes, Dipnoi, Amphibia, Reptiles, Birds, and Mammals. Although zoologists differ very widely in their opinions as to the affinities of this ancestral form, they all agree in maintaining that it did not arise direct from the Nematophora in the lower sub-grade of Metazoa, but that it was the product of a long history within the Cœlomate sub-grade. The question as to which of the other Cœlomate Phyla it was associated with will form the subject of one of our discussions at this meeting; and I will therefore say no more upon this period of its evolution, except to point out that the very question itself, "the ancestry of Vertebrates," only means a relatively small part of the evolutionary history of the Vertebrate ancestor within the Cœlomate group. For when we have decided the question of the other Cœlomate Phylum or Phyla to which the ancestral Vertebrate belonged, there remains of course the history of that Phylum or those Phyla earlier than the point at which the Vertebrate diverged, right back to the origin of the Cœlomata; while, beyond and below, the wide gulf between this and the Cœlentera had to be crossed, and then, probably after a long history as a Cœlenterate, the widest and most significant of all the morphological intervals—that between the lowest Metazoon and the highest Protozoon—was traversed. But this was by no means all. There remains the history within the higher Protozoan sub-grade, in the interval from this to the lower, and within the lower sub-grade itself, until we finally retrace our steps to the lowest and simplest forms. It is impossible to suppose that all this history of change can have been otherwise than immensely prolonged; for it will be shown below that all the available evidence warrants the belief that the changes during these earlier phases were at least as slow as those which occurred later.

If we take the history of another of the higher Phyla, the Appendiculata, we find that the evidence points in the same direction. The common ancestor of our Rotifera, earthworms, leeches, Peripatus, centipedes, insects, Crustacea, spiders and scorpions, and forms allied to all these, is generally admitted to have been Chætopod-like, and probably arose in relation to the beginnings of certain other Cœlomata Phyla, such as the Gephyrea and perhaps Mollusca. At the origin of the Cœlomate sub-grade, the common ancestor of all Cœlomate Phyla is reached, and its evolution has been already traced in the case of the Vertebrata.

What is likely to be the relation between the time required for the evolution of the ancestor of a Cœlomate Phylum and that required for the evolution, which subsequently occurred, within the Phylum itself? The answer to this question depends mainly upon the rate of evolution in the lower parts of the animal kingdom as compared with that in the higher. Contrary, perhaps, to anticipation, we find that all the evidences of rapid evolution are confined to the most advanced of the smaller groups within the highest Phyla, and especially to the higher classes of the Vertebrata. Such evidence as we have strongly indicates the most remarkable persistence of the lower animal types. Thus in the class Imperforata of the Reticularia (Foraminifera) one of our existing genera (*Saccamina*) occurs in the Carboniferous strata, another (*Trochammina*) in the Permian, while a single new genus (*Receptaculites*) occurs in the Silurian and Devonian. The evidence from the class Perforata is much stronger, the existing genera *Nodosaria*, *Dentalina*, *Textularia*, *Grammostomum*, *Valvulina*, and *Nummulina* all occurring in the Carboniferous, together with the new genera *Archædiscus* (?) and *Fusulina*.

I omit reference to the much-disputed Eozoon from the Laurentian rocks far below the horizon, which for the purpose of this address I am considering as the lowest fossiliferous stratum. We are looking forward to the new light which will be thrown upon this form in the communication of its veteran defender, Sir William Dawson, whom we are all glad to welcome.

Passing the Radiolaria, with delicate skeletons less suited for fossilisation, and largely pelagic and therefore less likely to reach the strata laid down along the fringes of the continental areas, the next Phylum which is found in a fossil state is that of the Porifera, including the sponges, and divided into two classes, the Calcispongiæ and Silicospongiæ. Although the fossilisation of sponges is in many cases very incomplete, distinctly recognisable traces can be made out in a large number of strata. From these we know that representatives of all the groups of both classes (except the Halisarcidæ, which have no hard parts) occurred in the Silurian, Devonian, and Carboniferous systems. The whole Phylum is an example of long persistence with extremely little change. And the same is true of the Nematophora: new groups indeed come in, sometimes extremely rich in species, such as the Palæozoic Rugose corals and Graptolites; but they existed side by side with representatives of existing groups, and they are not in themselves primitive or ancestral. A study of the immensely numerous fossil corals reveals no advance in organisation, while researches into the structure of existing Alcyonaria and Hydrocorallina have led to the interpretation of certain Palæozoic forms which were previously obscure, and the conclusion that they find their place close beside the living species.

All available evidence points to the extreme slowness of progressive evolutionary changes in the Cœlenterate Phyla, although the Protozoa, if we may judge by the Reticularia (Foraminifera), are even more conservative.

When we consider later on the five Cœlomate Phyla which occur fossil, we shall find that the progressive changes were slower and indeed hardly appreciable in the two lower and less complex Phyla, viz. the Echinoderma and Gephyrea, as compared with the Mollusca, Appendiculata, and Vertebrata.

Within these latter Phyla we have evidence for the evolution of higher groups presenting a more or less marked advance in organisation. And not only is the rate of development more rapid in the highest Phyla of the animal kingdom, but it appears to be most rapid when dealing with the highest animal tissue, the central nervous system. The chief, and doubtless the most significant, difference between the early Tertiary mammals and those which succeeded them, between the Secondary and Tertiary reptiles, between man and the mammals most nearly allied to him, is a difference in the size of the brain. In all these cases an enormous increase in this, the dominant tissue of the body, has taken place in a time which, geologically speaking, is very brief.

When speaking later on upon the evolution which has taken place within the Phyla, further details upon this subject will be given, although in this as in other cases, the time at our disposal demands that the exposition of evidence must largely yield to an exposition of the conclusions which follow from its study. And undoubtedly a study of all the available evidence points very strongly to the conclusion that in the lower grade, sub-grades, and Phyla of the animal kingdom, evolution has been extremely slow as compared with that in the higher. We do not know the reason. It may be that this remarkable persistence through the stratified series of deposits is due to an innate fixity of constitution which has rigidly limited the power of variation; or, more probably perhaps, that the lower members of the animal kingdom were, as they are now, more closely confined to particular environments, with particular sets of conditions, with which they had to cope, and, this being successfully accomplished, natural selection has done little more than keep up a standard of organisation which was sufficient for their needs; while the higher and more aggressive forms ranging over many environments, and always prone to encounter new sets of conditions, were compelled to undergo responsive changes or to succumb. But whatever be the cause, the fact remains, and is of the highest importance for our argument. When the ancestor

of one of the higher Phyla was associated with the lower Phyla of the Cœlomate sub-grade, when further back it passed through a Cœlenterate, a higher Protozoan, and finally a lower Protozoan phase, we must believe that its evolution was probably very slow as compared with the rate which it subsequently attained. But this conclusion is of the utmost importance; for the history contained in the stratified rocks nowhere reveals to us the origin of a Phylum. And this is not mere negative evidence, but positive evidence of the most unmistakable character. All the five Cœlomate Phyla which occur fossil appear low down in the Palaeozoic rocks, in the Silurian or Cambrian strata, and they are represented by forms which are very far from being primitive, or, if primitive, are persistent types, such as Chiton, which are now living. Thus Vertebrata are represented by fishes, both sharks and ganoids; the Appendiculata by cockroaches, scorpions, Limulids, Trilobites, and many Crustacea; the Mollusca by Nautilus and numerous allied genera, by Dentalium, Chiton, Pteropods, and many Gastropods and Lamellibranchs; the Gephyrea by very numerous Brachiopods, and many Polyzoa; the Echinoderma by Crinoids, Cystoids, Blastoids, Asteroids, Ophiuroids, and Echinoids. It is just conceivable, although, as I believe, most improbable, that the Vertebrate Phylum originated at the time when the earliest known fossiliferous rocks were laid down. It must be remembered, however, that an enormous morphological interval separates the fishes which appear in the Silurian strata from the lower branches, grades, and classes of the Phylum in which Balanoglossus, the Ascidians, Amphioxus, and the Lampreys are placed. The earliest Vertebrates to appear are, in fact, very advanced members of the Phylum, and, from the point of view of anatomy, much nearer to man than to Amphioxus. If, however, we grant the improbable contention that so highly organised an animal as a shark could be evolved from the ancestral vertebrate in the period which intervened between the earliest Cambrian strata and the Upper Silurian, it is quite impossible to urge the same with regard to the other Phyla. It has been shown above that when these appear in the Cambrian and Silurian, they are flourishing in full force, while their numerous specialised forms are a positive proof of a long antecedent history within the limits of the Phylum.

If, however, we assume for a moment that the Phyla began in the Cambrian, the geologist's estimate must still be increased considerably, and perhaps doubled, in order to account for the evolution of the higher Phyla from forms as low as many which are now known upon the earth; unless, indeed, it is supposed, against the whole weight of all such evidence as is available, that the evolutionary history in these early times was comparatively rapid.

To recapitulate, if we represent the history of animal evolution by the form of a tree, we find that the following growth took place in some age antecedent to the earliest fossil records, before the establishment of the higher Phyla of the Animal Kingdom. The main trunk, representing the lower Protozoa divided, originating the higher Protozoa; the latter portion again divided, probably in a threefold manner, originating the two lowest Metazoan Phyla, constituting the Cœlentera. The branch representing the higher of these Phyla, the Nematophora, divided, originating the lower Cœlomate Phyla, which again branched and originated the higher Phyla. And, as has been shown above, the relatively ancestral line, at every stage of this complex history, after originating some higher line, itself continued down to the present day, throughout the whole series of fossiliferous rocks, with but little change in its general characters, and practically nothing in the way of progressive evolution. Evidences of marked advance are to be found alone in the most advanced groups of the latest highest products—the Phyla formed by the last of these divisions.

It may be asked how is it possible for the zoologist to feel so confident as to the past history of the various animal groups? I have already explained that he does not feel this confidence as regards the details of the histoyr, but as to its general lines. The evidence which leads to this conviction is based upon the fact that animal structure and mode of development can be, and have been, handed down from generation to generation from a period far more remote than that which is represented by the earliest fossils; that fundamental facts in structure and development may remain changeless amid endless changes of a more general character; that especially favourable conditions have preserved ancestral forms comparatively unchanged. Working upon this material, comparative anatomy and embryology can reconstruct for us the general aspects of a history which took place long before the Cambrian rocks were deposited. This line of reasoning may appear very speculative and unsound, and it may easily become so when pressed too far. But applied with due caution and reserve, it may be trusted to supply us with an immense amount of valuable information which cannot be obtained in any other way. Furthermore, it is capable of standing the very true and searching test supplied by the verification of predictions made on its authority. Many facts taken together lead the zoologist to believe that A was descended from C through B; but if this be true, B should possess certain characters which are not known to belong to it. Under the inspiration of hypothesis a more searching investigation is made, and the characters are found. Again, that relatively small amount of the whole scheme of animal evolution which is contained in the fossiliferous rocks has furnished abundant confirmation of the validity of the zoologist's method. The comparative anatomy of the higher Vertebrate Classes leads the zoologist to believe that the toothless beak and the fused caudal vertebræ of a bird were not ancestral characters, but were at some time derived from a condition more comfortable to the general plan of vertebrate construction, and especially to that of reptiles. Numerous secondary fossils prove to us that the birds of that time possessed teeth and separate caudal vertebræ, culminating in the long lizard-like tail of Archæopteryx.

Prediction and confirmation of this kind, both zoological and palæontological, have been going on ever since the historic point of view was adopted by the naturalist as the outcome of Darwin's teaching, and the zoologist may safely claim that his method, confirmed by palæontology so far as evidence is available, may be extended beyond the period in which such evidence is to be found.

And now our last endeavour must be to obtain some conception of the amount of evolution which has taken place within the higher Phyla of the Animal Kingdom during the period in which the fossiliferous rocks were deposited. The evidence must necessarily be considered very briefly, and we shall be compelled to omit the Vertebrata altogether.

The Phylum Appendiculata is divided by Lankester into three branches, the first containing the Rotifera, the second the Chætopoda, the third the Arthropoda. Of these the second is the oldest, and gave rise to the other two, or, at any rate, to the Arthropoda, with which we are alone concerned, inasmuch as the fossil records of the others are insufficient. The Arthropoda contain seven Classes, divided into two grades, according to the presence or absence of antennæ—the Ceratophora, containing the Peripatoidea, the Myriapoda, and the Hexapoda (or insects); the Acerata, containing the Crustacea, Arichnida, and two other classes (the Pantopoda and Tardigrada) which we need not consider The first Class of the antenna-bearing group contains the single genus Peripatus—one of the most interesting and ancestral of animals, as proved by its structure and development, and by its immense geographical range. Ever since the researches of Moseley and Balfour, extended more recently by those of Sedgwick, it has been recognised as one of the most beautiful of the connecting links to be found amongst animals, uniting the antenna-bearing Arthropods, of which it is the oldest member, with the Chætopods. Peripatus is a magnificent example of the far-reaching conclusions of zoology, and of its superiority to palæontology as a guide in unravelling the tangled history of animal evolution. Peripatus is alive to-day, and can be studied in all the details of its structure and development; it is infinitely more ancestral, and tells of a far more remote past than any fossil Arthropod, although such fossils are well known in all the older of the Palæozoic rocks. And yet Peripatus is not known as a fossil. Peripatus has come down, with but little change, from a time, on a moderate estimate, at least twice as remote as the earliest known Cambrian fossil. The agencies which, it is believed, have crushed and heated the Archæan rocks so as to obliterate the traces of life which they contained were powerless to efface this ancient type, for, although the passing generations may have escaped record, the likeness of each was stamped on that which succeeded it, and has continued down to the present day. It is, of course, a perfectly trite and obvious conclusion, but not the less one to be wondered at, that the force of heredity should thus far outlast the ebb and flow of terrestrial change throughout the vast period over which the geologist is our guide.

If, however, the older Palæozoic rocks tell us nothing of the origin of the antennæ-bearing Arthropods, what do they tell us of the history of the Myriapod and Hexapod Classes?

The Myriapods are well represented in Palæozoic strata, two species being found in the Devonian and no less than thirty-two

in the Carboniferous. Although placed in an Order (Archipolypoda) separate from those of living Myriapods, these species are by no means primitive, and do not supply any information as to the steps by which the Class arose. The imperfection of the record is well seen in the traces of this Class; for between the Carboniferous rocks and the Oligocene there are no remains of undoubted Myriapods.

We now come to the consideration of insects, of which an adequate discussion would occupy a great deal too much of your time. An immense number of species are found in the Palæozoic rocks, and these are considered by Scudder, the great authority on fossil insects, to form an Order, the Palæodictyoptera, distinct from any of the existing Orders. The latter, he believes, were evolved from the former in Mesozoic times. These views do not appear to derive support from the wonderful discoveries of M. Brongniart [1] in the Upper Carboniferous of Commentry in the Department of Allier in Central France. Concerning this marvellous assemblage of species, arranged by their discoverer into 46 genera and 101 species, Scudder truly says:

"Our knowledge of Palæozoic insects will have been increased three or fourfold at a single stroke. . . . No former contribution in this field can in any way compare with it, nor even all former contributions taken together." (S. H. Scudder, *Am. Journ. Sci.*, vol. xlvii., February 1894, Art. viii.)

When we remember that the group of fossil insects, of which so much can be affirmed by so great an authority as Scudder, lived at one time and in a single locality, we cannot escape the conclusion that the insect fauna of the habitable earth during the whole Palæozoic period was of immense importance and variety. Our knowledge of this single group of species is largely due to the accident that coal-mining in Commentry is carried on in the open air.

Now, these abundant remains of insects, so far from upholding the view that the existing orders had not been developed in Palæozoic times, are all arranged by Brongniart in four out of the nine orders into which insects are usually divided, viz. the Orthoptera, Neuroptera, Thysanoptera, and Homoptera. The importance of the discovery is well seen in the Neuroptera, the whole known Palæozoic fauna of this order being divided into 45 genera and 99 species, of which 33 and 72 respectively have been found at Commentry.

Although the Carboniferous insects of Commentry are placed in new families, some of them come wonderfully near those into which existing insects are classified, and obviously form the precursors of these. This is true of the Blattidæ, Phasmidæ, Acridiidæ, and Locustidæ among the Orthoptera, the Perlidæ among the Neuroptera, and the Fulgoridæ among the Homoptera. The differences which separate these existing families from their Carboniferous ancestors are most interesting and instructive. Thus the Carboniferous cockroaches possessed ovipositors, and probably laid their eggs one at a time, while ours are either viviparous or lay their eggs in a capsule. The Protophasmidæ resemble living species in the form of the head, antennæ, legs, and body; but while our species are either wingless or, with the exception of the female Phyllidæ, have the anterior pair reduced to tegmina, useless for flight, those of Palæozoic times possessed four well-developed wings. The forms representing locusts and grasshoppers (Palæacrididæ) possessed long slender antennæ like the green grasshoppers (Locustididæ), from which the Acridiidæ are now distinguished by their short antennæ. The divergence and specialisation which is thus shown is amazingly small in amount In the vast period between the Upper Carboniferous rocks and the present day the cockroaches have gained a rather different wing venation, and have succeeded in laying their eggs in a manner rather more specialised than that of insects in geneial; the stick insects and leaf insects have lost or reduced their wings, the grasshoppers have shortened their antennæ. These, however, are the insects which most closely resemble the existing species; let us turn to the forms which exhibit the greatest differences. Many species have retained in the adult state characters which are now confined to the larval stage of existence, such as the presence of tracheal gills on the sides of the abdomen. In some the two membranes of the wing were not firmly fixed together, so that the blood could circulate freely between them. On the other hand, they are not very firmly fixed together in existing insects. Another important point was the condition of the three thoracic segments, which were quite distinct and separate, instead of being fused as they are now in the imago stage. This external difference probably also extended to the nervous system, so that the thoracic ganglia were separate instead of concentrated The most interesting distinction, however, was the possession by many species of a pair of prothoracic appendages much resembling miniature wings, and which especially suggest the appearance assumed by the anterior pair (tegmina) in existing Phasmidæ. There is some evidence in favour of the view that they were articulated, and they exhibit what appears to be a trace of venation. Brongniart concludes that in still earlier strata, insects with six wings will be discovered, or rather insects with six of the tracheal gills sufficiently developed to serve as parachutes. Of these, the two posterior pair developed into the wings as we know them, while the anterior pair degenerated, some of the Carboniferous insects presenting us with a stage in which degeneration had taken place, but was not complete.

One very important character was, as I have already pointed out, the enormous size reached by insects in this distant period. This was true of the whole known fauna as compared with existing species, but it was especially the case with the Protodonata, some of these giant dragon-flies measuring over two feet in the expanse of the wings.

As regards the habits of life and metamorphoses, Brongniart concludes that some species of Protoephemeridæ, Protoperlidæ, &c., obtained their food in an aquatic larval stage, and did not require it when mature. He concludes that the Protodonata fed on other animals, like our dragon-flies; that the Palæacrididæ were herbivorous like our locusts and grasshoppers, the Protolocustidæ herbivorous and animal feeders like our green grasshoppers, the Palæoblattidæ omnivorous like our cockroaches. The Homoptera, too, had elongated sucking mouth-parts like the existing species. It is known that in Carboniferous times there was a lake with rivers entering it, at Commentry. From their great resemblance to living forms of known habits, it is probable that the majority of these insects lived near the water and their larvæ in it.
